In a late issue of one of the leading German forest-periodicals, Wilhelm Kessler, a Prussian forest-officer, gives an account of his journey through the forests of Mexico and the United States. He describes a large forest of the Monterey Pine on the coast of California, which is carefully protected by the proprietor. Again, in a remarkable and most interesting book on the forests of North America, just published, the author, Dr. Heinrich Mayr, now Professor of Forestry at the Imperial Forest School of Japan, mentions his rides through large areas of virgin forest, kept in reserve by timber speculators and carefully protected until their turn comes to be cut down. Here, then, we have the first beginning of regular management, consisting in protection and successive cuttings. The second step is thus to arrange matters that on the places where cuttings have been made, young forest, consisting of the valuable species, shall grow up, so that when the last piece of the old forest has been cut down, a sufficient area of second growth with timber of the kind and size required may be ready for cutting. These arrangements will be facilitated by the great reproductive powers which some of the more important American forest-trees possess. In that portion of his book which treats of the forests in the Atlantic region, Dr. Mayr gives an account of the manner in which the White Pine (*Pinus strobus*) reproduces readily from self-sown seed, wherever climatic and other conditions are favorable for its development. Regarding the Douglas Fir, the author states facts which show that under favorable conditions complete forests of second growth are produced from self-sown seed. Wilhelm Kessler, in the paper quoted, states the same for the Yellow Pine (*Pinus ponderosa*). Hence it will be possible, if due care is taken in arranging the cuttings and in the subsequent treatment of the forest, to secure the regeneration, by self-sown seed, of valuable woods. To this primary object the attention of all those who are engaged in forest-operations in North America should be directed. It is only by actual experience and by series of experiments conducted on a regu-

lar system that the question can be solved, how cuttings should be arranged and what treatment should be adopted in order to produce a complete crop of young trees of the particular kind desired. Such arrangement of cuttings and such system of treatment will, as a matter of course, be different for each kind of tree, and will also differ according to soil and situation. Nor will it be feasible in all cases to secure a renewed crop from self-sown seedlings alone. Nature must be assisted in various ways, by hoeing the ground or otherwise, and in many instances by sowing and planting, in order to attain the object aimed at.

To these matters the labors of foresters in Germany, in France and in other countries of Europe have long been directed, and the result has been that in these countries the art of managing forests has gradually developed into a profession, analogous to the profession of law or of medicine. The fundamental principles of jurisprudence are as plain and as easily intelligible as the fundamental principles which underlie the profession of a forester. The application of these principles, however, is a difficult and complicated business. Just as it requires much study to master the profession of a lawyer, so it is with forestry. Again, just as the profession of medicine is based upon many branches of natural science, such as chemistry, physics, anatomy and physiology, so also an efficient forester ought to be at home in mathematics, botany, chemistry, geology and other exact sciences.

Evidently, therefore, manuals are needed to facilitate the study of forestry, and the work of which the title appears at the head of this article is the first comprehensive manual of forestry that has appeared in the English language. The author, Dr. William Schlich, is one of two German forest-officers whom the writer, while Inspector-General of Forests in India, was permitted to engage for the Indian Forest Service. Before going out to India in 1866, Dr. Schlich had passed the examinations for the superior forest-service in his own country (Hesse-Darmstadt), he had been the pupil of one of the most eminent professors of forestry in Germany, the late Gustav Heyer, and he held a distinguished place among his fellow students. In India he was designated at an early date for important positions; he served successively in several provinces until he rose to the post of Inspector-General of Forests. This important position he consented to relinquish in 1885, in order to take up the appointment of Principal Professor of Forestry at the English Forest School which it had been decided to form in connection with the Royal Indian Engineering College at Cooper's Hill.

The first volume of the Manual contains the general and introductory part; in a second volume the author proposes to set forth in detail the different silvicultural operations; while the protection of forests, the utilization of timber and other forest-produce, the systematic arrangement of the plans for working and the financial aspect of forest-management will complete the work. Not the least of the advantages which will be gained by the publication of this Manual will be to settle the English forest terminology. When methodical forest-management was begun in India some thirty-four years ago, it was necessary to devise terms for matters connected with the treatment of forests for which, at that time, no convenient expressions existed in the English language. The technical terms which then were tentatively used, may now, through the publication of this Manual, be expected to receive general currency, while in some cases more suitable terms will be substituted for those originally used.

Hardy Plants at Short Hills, New Jersey.

To the Editor of GARDEN AND FOREST:

Sir.—A few days of genial weather has brought rapidly forward the early spring flowers, and I found in Messrs. Pitcher & Manda's nursery many interesting plants in bloom. The hardy plant department of this establishment is at some distance from the greenhouses, on the main road near the railroad station, and the situation is well adapted to such a nursery, being rolling ground with various exposures, and sloping at one point to a small stream. One notices, on entering the grounds, that a long, wide border has been made along the highway and filled with an assortment of plants for the benefit of the public. Varieties of *Phlox subulata* (Moss Pink) brightened up the beds near the entrance with masses of flowers which entirely hid the foliage. Excellent plants for spring carpeting they are, though some of the reds are not quite pleasing. A *Phlox* of more recent introduction is the white

P. Stellaria, dwarf in habit and not so compact in bloom. The first flowers of the Iceland Poppy (*Papaver nudicaule*) were just expanding. This dwarf Poppy is a gem, but it is apt to exhaust itself by profuse blooming, so that it cannot be considered a true perennial. It is best treated as a biennial for early bloom. If sown early in the year it will bloom in late summer and again in the following spring. The single flowers are white, yellow and orange. The well known white-flowered *Arabis Alpina* is here growing finely in a level border, though usually considered at home on the rockery. *Hepatica triloba rubra* has a color effect similar to that of the reddish Pink (*P. subulata*). *Myosotis elegantissima*, a variety of *M. alpestris*, is compact, with light blue flowers. *M. sylvatica compacta* has the compact habit and the yellowish foliage dear to the lover of variegated things. Varieties of *Doronicums* in bloom show that *D. plantagineum*, var. *excelsum*, is far away the best of the family and one of the best yellow Composites. Harpur Crewe, before noted in GARDEN AND FOREST, is a garden variety of this species. *Dodecatheon Meadia* and the rose-flowered *D. Jeffreyi*, *Anemone patens Nuttalliana*, *Viola cucullata* and its white variety, the lovely little *Iris cristata*, and *Stylophorum diphyllum*, the Celandine Poppy, were a few native plants worthy of any border.

Lovers of Aquatics will be interested in a *Caltha palustris* with a large, very double Ranunculus-like flower. *Helonias bullata* is not one of the most attractive marsh plants; but its rosy purple spike of flowers is rather interesting. Among the Primulas in bloom was a good strain of Polyanthus, *P. Auricularis*, *P. farinosa* and *P. Peyritschii*, the latter a hybrid between *P. auricula* and *P. viscosa*, a deep rosy flower with a white eye. *Epimedium macranthum* is a charming Barrenwort, as seen blooming here in young plants; the stems delicate, foliage pleasing and white flowers very attractive. A marked contrast is *Geum triflorum*, with its scapes bearing three purplish red, closed flowers—a native curiosity. The white *Orobis vernus* and violet-blue *O. lathyroides* are two good spring Vetches. Other plants noticed in bloom were a double *Cardamine pratensis*, the Cuckoo Flower; *Iberis Gibraltarica*, the perennial Candytuft (is this reliably hardy here as reported lately in GARDEN AND FOREST?); *Corydalis nobilis*; *Stellaria Holostea* (Satin flower), white flower, neat foliage; *Veronica repens*, dwarf, deep blue flowers; *Ajuga alpina*, a neat rockery plant; *Iris nudicaulis*; *Pulmonaria officinalis* and *Polemonium reptans*, two good old border plants; *Actæa spicata*; *Wulfenia fragrans*; *Arnebia echtioides*, with showy yellow flowers; *Glechoma hederacea*, var., a neat, creeping plant with violet flowers, and useful in baskets, etc.

It was a pleasure to find such a variety of good flowers where, of course, no effort is made to show blooms, and to hear that the demand for hardy flowering plants is increasing; but it is to be feared that the demand is not a tithe of what it should be and must become when these attractive plants are more generally made known; and, it may be added, when the average gardener ceases to turn over every border in April and grub out all plant-life. The railroad to Short Hills runs through miles of our most populous suburbs, and is lined with handsome, detached villas, evidently the homes of country-loving, prosperous people. I had the curiosity to look from a not very fast running train for some color from hardy flowers, but in all the distance from the city, with the exception of the blossoming fruit-trees, a few shrubs and a patch of *Phlox subulata* in a graveyard, not a glint of color from a hardy plant could be seen, though miles of well kept grounds were open to view. This seems to tell a pretty plain story about the limited distribution of spring-flowering plants.

About Grafting.

To the Editor of GARDEN AND FOREST :

Sir.—I entirely agree with Mr. Burbidge when he says (page 158) that "Mr. Parsons does not go quite to the bottom of this question of grafting." There are many aspects of the problem which I should like to see illumined, and I was disappointed because Mr. Burbidge did not think it worth while to throw any new light upon the subject. He simply asserts that we do not know that grafting fruit-trees is better than growing them on their own roots, because the two processes have never been tried side by side. Of course, by the same reasoning, we do not know that the trees on their own roots are better, and until Mr. Burbidge proves that they are, it might be prudent for him to modify his absolute condemnation of grafting. If Mr. Burbidge proves anything by the assertion that "Nature is ahead of the most successful gardener, and she does not graft her productions," he proves too much, because the same argument would condemn layering, growing from cuttings, and even the

transplanting of seedlings, for Nature does none of these things. And what is the bearing of the statement that the Seckel Pear was not grafted, but was a chance seedling? Has any one advocated grafting as a means of securing new varieties? If we assume that Nature produced the Seckel Pear this means that out of the millions of natural seedlings one individual has proved of supremely good quality. But how long would it take Nature to produce an orchard full of Seckel Pears? If the variety had not been perpetuated by grafting and budding, Mr. Burbidge would probably never have tasted one. But as a matter of fact Nature did not produce the Seckel Pear. The seed from which the tree sprang was undoubtedly produced from varieties which man had been improving for centuries by selection and perpetuating by grafts.

S. B. Parsons.

A Large Purple Beech.

To the Editor of GARDEN AND FOREST :

Sir.—In your issue of May 8th, 1889, there was an interesting article upon a noteworthy Purple Beech upon the Lyman Place, Waltham. In that article it was said: "It would be interesting to know if there are large or very fine specimens of the Purple Beech in the neighborhood of this city or Philadelphia." A few days since I visited a Purple Beech on the grounds of Mr. Wm. H. Dyer, of Johnston, Rhode Island, which is certainly a fine tree. The tree was set in its present location in 1829 by the father of the present owner, Mr. Daniel P. Dyer, who was one of the pioneer tree-growers of this state; and he beautified his own grounds, as well as those of many of the fine old estates of Providence and vicinity, with some of the choicest kinds of trees which will grow in this climate.

The Beech alluded to is notable for its symmetry, presenting, in leaf, an almost perfect mound of dark purple foliage. Its dimensions, as ascertained by careful measurement, are as follows: Spread of limbs in two directions, nearly right angles, seventy-four and sixty-eight feet respectively; height, fifty feet, nearly; circumference of bole, three feet from the ground, ten feet four inches. At five feet from the ground, where the main stem divides into three parts, it is eleven feet in girth.

The tree is now in vigorous condition, and promises to grow much larger if it does not split apart at the place of its triple division, where it is now secured by iron bolts.

Near by this tree is a beautiful Cut-leaved Beech of large size, and a *Cladrastis lutea*, forty or more feet high, and of wide spread.

Providence, R. I.

L. W. Russell.

Evergreens Destroyed by Fire.

To the Editor of GARDEN AND FOREST :

Sir.—All persons do not realize that evergreen-trees are very liable to injury from fire when grass, leaves or other litter is permitted to burn in their vicinity during a dry time. Last spring a fine Norway Spruce hedge on the farm of the Wisconsin Agricultural Experiment Station was accidentally set on fire from a mass of burning leaves in the neighborhood, and before the fire could be extinguished several rods of the hedge were totally destroyed. The heat created was sufficient to seriously damage some fine shade-trees that were standing near. Last October, while visiting the orchards of Mr. A. G. Tuttle, of Baraboo, Wisconsin, I saw several fine groups of evergreens on his grounds suffer total destruction from fire through the ignorance and carelessness of some of his men who had been instructed to burn some brush in the vicinity. The fire ran through the partially dried grass that covered the ground about the trees, and as it approached their trunks, the dry needles beneath the trees, being resinous, burned so vigorously that the lower branches were ignited, and in a moment the fire crept up the trunk to the top of the tree, where tongues of flame rose higher than the tallest shoots. Whole groups of Norway Spruces, Balsam Firs and Scotch Pines, nearly or quite twenty feet in height, were destroyed in a moment by a roaring conflagration.

University of Wisconsin.

E. S. Goff.

Notes.

The shipment of California wines to New York for this year amounts to 150,000 gallons.

A winter-garden has recently been added to Craig-y-nos, Madame Patti's castle in Wales, at a cost of \$20,000.

The cable announces the death of Mr. Hugh Low, the senior member of the successful London nursery firm of Hugh Low & Sons, large importers and dealers in Orchids.

Carnations have been scarce and high priced during all of the late flower-season. They have ranged in price from \$2 to \$2.50 a hundred, when generally they are not over \$1 or \$1.25 a hundred.

In those portions of Spain where the Cork Oak (*Quercus Suber*) is abundant, it is said that the peasants use the cork to line their houses. Naturally it is an effectual protection against dampness.

Contrary to general prediction the season has proved an uncommonly productive one for Maple orchards in some states. A correspondent of the *Country Gentleman* estimates that the yield of Maple Syrup in the Western Reserve will reach 600,000 tons.

According to a Mahometan legend, Eve picked a four-leaved Clover as she was driven from Paradise. But the angel's sword touched her, and its leaves were scattered. One of them fell within the garden, while the others were blown outside. Hence the rarity of the four-leaved form and the luck which attends its discovery.

One of the recent introductions of Monsieur Lemoine, the famous horticulturist of Nancy, is a variety of Heliotrope which foreign journals declare to be more nearly white than any previously known variety, including the White Lady. It is a hybrid between *Heliotropium Peruvianum* and *H. incanum*, and has been named "Fleur d'été."

In many Austrian provinces the Christmas Rose (*Helleborus niger*) grows wild among the mountains, blooming in the month of February. But within the past few years such large numbers of the plants have been uprooted for exportation to other parts of Germany, to England and even to America that local journals deplore the prospect of its possible extermination.

The show of Tulips in the New York parks has been unusually fine this year. There have been no successors among them of the dull purplish flowers which prevailed last year, but a brilliant assemblage of clear red, yellow and white flowers. The circle at the Fifth Avenue entrance of the Central Park was especially gorgeous, and everywhere the blossoms appeared simultaneously and have lasted well.

The largest of the edible gourds tested by Dr. Harris is the Kampiyo, of Okayama, Japan, which grows a yard long and five or more inches thick, and in Japan reaches a weight of sixty or seventy pounds. The Japanese dry it before it is cooked; it may be sliced and fried like egg-plant, and is equal in flavor to a good squash. The plant is hardy, productive and without musk odor, and Squash bugs do not seem to be fond of it.

The *California Fruit Grower* says that a delightful syrup can be made from Watermelons by chopping them, pressing out the juice, and boiling it for several hours. The red coloring matter then coagulates, rises to the surface, and is skimmed off, when the juice remains "as clear as distilled water and of a pale amber color. Boiled a little longer, it thickens into a rich, fruity-flavored syrup, perfectly clear and the color of quince or apple jelly."

A writer in a German horticultural journal ventures the statement, for which he cites the authority of F. Cohn, that wild Grape-vines are sometimes found in the Maremma of Tuscany whose stems measure more than three feet in diameter, and adds that they can be found of still larger size in the Caucasian Mountains. The largest Grape-vine in cultivation, the famous one at Hampton Court, is only thirty inches in circumference at three feet above the ground.

We have already noticed the manufacture of cloth from Pine-needles as a promising young industry in some of our southern states. A correspondent of the *Atlanta Constitution*, writing from Wilmington, North Carolina, says that at a factory in a neighboring village may be seen specimens of colored matings made from the "Pine straw," which are excellent in quality and also attractive in appearance, as the straw can be bleached to a fine creamy tint and readily takes brilliant dyes. But the machinery for making this matting lies idle, so great is the demand for coarse cloth for cotton bagging.

The *Interstate Grocer* calls attention to the danger which threatens the California dried-fruit industry from the dishonest methods employed by many shippers. Prunes, which the producer sells in boxes bearing a number that indicates how many fruits go to the pound, are repacked in deceptive ways; and old prunes which have been treated to give them a fresh appearance are mixed with the new. Old currants, too, are "steamed,

syruped, mixed, repacked and sold as new;" and, moreover, the shipping marks of reputable importers are forged on the fruit-boxes. Our contemporary advises retailers to weigh fruit carefully before purchasing, or, better still, to buy the prunes which come in sacks instead of those in boxes.

We have just received a sketch of the life and services to American horticulture of the late Peter Henderson, which was read before the New York Florists' Club by Mr. A. D. Cowan. One of the interesting facts brought out in this paper is that when "Gardening for Profit" was prepared Mr. Henderson was occupied with his business for sixteen hours a day and the book was written in the short noon intervals and in the small night hours. The author wrote lying on his back with his head bolstered up to rest his body while his active mind kept at work. We quote this not so much to show Mr. Henderson's industry and energy as to call attention to the fact that this most successful of all his books, and probably the most useful work on market-gardening ever published, was written directly from the author's personal and daily experience. Perhaps this will help to account for its high practical value.

Timber thieves had become so numerous in Burlington and Ocean Counties, New Jersey, that, a few years ago, a Timber Protective Society was established, which employed detectives to patrol the woodland tracts in many townships. Of late this precaution has been abandoned, and the thieves have again become so bold that fresh measures are being taken to combat them. A correspondent of the *New York Tribune* recently wrote: "A few days ago an owner paid a visit to his tract of Cedar swamp, a few miles from Pemberton, Burlington County, with the idea of having it cut and converted into lumber. From the outside the swamp seemed to be in good condition, but, on pushing through the underbrush a short distance, he was surprised to find that the tract had been stripped. Nearly all the best timber had been cut and carried off. Hundreds of tracts have been despoiled in this manner."

The hot-house peaches in market, although somewhat small in size, are of excellent quality and well ripened. They bring fifty cents each in the fruit-shops. Peen-to Peaches from Florida have been on sale for a fortnight; they are not of the best quality and have sold for twenty-five cents a quart. Black Hamburg and Muscat grapes sell for \$4 a pound; the Muscats are not as large as usual. Fine hot-house-grown Sharpless strawberries bring \$2.50 a cup, which contains sixteen berries, in spite of abundant receipts from the South. West India mangoes have just arrived, and being the first of this season's growth are very good, but not of a very large size; they sell for from seventy-five cents to \$1 a dozen. Porto Rico pines are just here; they are very much larger than the ordinary fruit, weighing from five to ten pounds each, and bring \$1.50 apiece. Grape-fruit will soon be out of season. More than twice the quantity has been sold here during the winter than during any previous year. The prevalent belief that it corrects malarial tendencies has largely increased its use.

Central Park is particularly attractive just now. The colors of the expanding leaves are quite as varied as those of autumn foliage, and the grass is unusually thick and green. Next to the Dandelions, which gem the turf everywhere, the most abundant wild flowers are the Spring Beauties, which, on some slightly shaded slopes, seem to have taken almost entire possession of the soil. In the natural wood, in the northern part of the park, there are great sheets of the cream-white flowers of Dicentra, and on exposed rocks the delicate panicles of the Early Saxifrage are opening in great abundance. For some cause the Dog's-tooth Violets, which usually bloom very freely in the park, show scarcely a flower this season. Many of the low-growing herbaceous perennials, which have been largely planted of late years, are now in flower, and masses of Moss Pink, Aubrietia, Rock Cress, Armeria, Stemless Gentian, Primroses, Stitchwort (*Stellaria Holostea*) or Epimedium can be found along almost any path or drive. In some places the masses are too large, glaring and obtrusive, but generally they are well placed. The stretch of Heather along the bridle-path near Eighty-second Street is particularly pleasing. Among the shrubs our native Spice-wood is blooming profusely; the Forsythias, especially those which were severely pruned last year, are doing fairly well, and Thunberg's Barberry is covered with flowers; but one misses the blaze of scarlet which the Japan Quince ought now to be displaying. This is one of the shrubs which has suffered from the open winter, as have the Hazels and Alders and the early-flowering Honeysuckles—*Lonicera fragrantissima* and *L. Standishii*.

The Greendale Oak and Welbeck Abbey.

A PORTRAIT of the Greendale Oak, representing the tree as it appears to-day, is published on page 239. The Greendale Oak is familiar by name at least to most persons who take any interest in the venerable or otherwise remarkable trees of England. It was a tree of such unusual size 176 years ago that the then Duke of Portland laid a wager that he had in his park at Welbeck a tree so large that he could drive a carriage and four through a hole cut in the trunk. He won his bet and ruined one of the most remarkable trees in Europe, which, in spite of this barbarous mutilation at the hands of the noble proprietor of Welbeck, has continued to exist almost in the same condition that it appears to have been in 1775, when the drawing of it was made that was published eleven years later in Hunter's edition of "Evelyn's Sylva." Another portrait of the tree appeared in Hayman Rook's "Description and Sketches of Some Remarkable Oaks in the Park at Welbeck," a rare and interesting book, published in London in 1790. Rook states that the Greendale Oak was "thought to be above 700 years old; and that, from its appearance, there is every reason to suppose that it had attained to that age at least." He gives the following statistics of its size: Circumference of the trunk above the arch, thirty-five feet three inches; height of the arch, ten feet three inches; width above the middle, six feet three inches; height of the top branch, fifty-four feet. The tree has probably increased very little since these measurements were made just a century ago, although we have not, unfortunately, any recent authoritative measurements with which to compare them. The archway, however, has certainly been much narrowed by the extension of the bark round the edges of the cut since the Duke drove his carriage and four through it. Another portrait, somewhat idealized, of the Greendale Oak appears on the title page of Strutt's noble "Sylva Britannica," in which are gathered the portraits of the most venerable and most interesting trees of Great Britain.

The Duke, who ruined this fine tree to win an after-dinner bet, was not the only eccentric owner, to use a very

mild expression, of Welbeck Abbey; and to the late Duke belongs the somewhat equivocal honor of having spent more money badly on a country estate than any man whose operations are accurately known. He enjoyed the title during twenty-five years only, but he spent in that time at Welbeck not less than \$35,000,000. Money was never spent more foolishly or with less results, and much of it disappeared underground. An old high-road crossed the park within sight of the windows of the Abbey. The Duke did not like his privacy encroached upon, so he carried the road through a tunnel a mile and a half long and leading right under the lake to a point where it could not be seen from the mansion, and where the traveler was allowed to emerge again into the light of day. This tunnel, arched with brick, made water-tight with cement and lighted day and night with gas, was an expensive affair. But the Duke, having once got the taste for burrowing, kept at it until he had made a vast picture gallery 158 feet long below the surface of the ground, connected with a great underground ball-room and joined with the mansion by long subways. Other subways lead to a great underground kitchen and to the stable a mile away. The conservatories were all underground, too, and the tired and astonished visitor may wander for miles through passages lighted only from occasional bull's-eyes placed at a level with the surface of the ground. Great sums of money were spent in building. A new wing was added to the Abbey, which was flanked by a broad, flat terrace leading down to the lake, a long, narrow sheet of artificial water, with margins bare of vegetation and marked by formal edge stones. A mile from the house and between it and the gardens are grouped a number of great stone buildings erected by the Duke. He never drove and rarely rode, but his stables had accommodations for 200 horses. The riding-school, the finest in Europe, it is said, is roofed with glass, and is 385 feet long and 104 feet wide. Eight thousand gas jets are provided to light it in case it is ever used at night. A tan gallop, enclosed in brick and covered with glass, 1,240 feet long, in which horses can be exercised in bad weather, stands near the riding-school; and not far away are coach-houses and farm-buildings, a poultry-yard, a timber-yard with a saw-mill, the house of the manager of the estate, and a club-house with a reading-room for the use of the working-people. The kitchen-garden and forcing establishment occupy eighteen acres, surrounded with a solid brick wall eighteen feet high. There are miles of glass in this enclosure, and some of the best fruit-trees in England. Seventy-five men keep this garden and the grounds about the mansion in order, and the work is well done. It would be hard to find a garden in better order or one more productive of good crops of fruit and vegetables of the highest quality; but outside the garden there is little of real interest on the estate.

The old Duke was all alone in the world. There was no one to help him waste his millions or to enjoy the results he thought he obtained; no kinsman or friend was allowed to cross his threshold; the only people he saw were the workmen who built up and pulled down at his command, and kept delving deeper and deeper into the ground. When his time came to die it was not even at Welbeck that the messenger found him. Was there ever a sadder spectacle of misdirected energy, of wasted fortune, of fruitless striving! That most of the money spent at Welbeck by this eccentric old man was wasted, there can be no doubt; for Welbeck Abbey, in spite of the millions which have been lavished on it, is one of the least attractive of the great homes of England. The house is set down in a hole, close to the ugly, formal lake, and the only view it commands is across the lake, and this view is ruined by a pair of ugly copper gates standing right in the middle distance, without other support than that afforded by a low metal boat-house. The view of this part of the park would, without this blot, be fine, as many such English park views are fine, from the natural grouping of the old trees they contain, and from the great bands of

deer which enliven them. But apart from this one view across the park, there is nothing at Welbeck to delight the eye of the lover of Nature or of natural beauty. The architecture is cold and monotonous, and the trees are, as a rule, small and in poor condition. Welbeck, however, as it exists, affords one of the most useful object-lessons in Europe, for it shows as no other country-place can show that the mere expenditure of money, unaided by taste and judgment, is powerless to accomplish any results in landscape-gardening of real or permanent value; and no American can see Welbeck and all its ghastly splendors without finding cause of congratulation for the laws and customs of his native land, which make such establishments impossible here. Welbeck is the principal although much the least interesting of the four great estates created on what was once Sherwood Forest (see page 197), and known as "the Dukeries."

It is rather a remarkable fact, which perhaps some of our readers will be able to explain, that there is now nowhere in the United States any one distinguished for a knowledge of cultivated Roses. Rosarians, as they are called in England, are common enough there, and their patient researches and their zeal in gathering and disseminating knowledge about Roses has been of the greatest service in increasing the taste for the cultivation of the queen of flowers. It is hardly conceivable that the rose does not hold the first place among flowers in the affection of the people of this country. She must still be queen by right and by tradition, although some newer favorites, like the *Chrysanthemum*, may appear to press her hard for a time. No people in the world buy so many roses as ours, and although fashion and love of display may have something to do with the great prices often paid for these flowers in winter, a real love of roses for their own sake is the true reason of their popularity.

American florists grow roses, especially under glass in winter, to perfection, and the best products of their skill are hardly to be matched anywhere. One can be a good commercial grower of roses and yet have only a limited knowledge of a comparatively few varieties, and the professional florist from a business point of view need only know how to draw from these the best money returns. What is really needed, however, in the interest of horticulture here is some one with leisure and opportunity to take up and carry on systematically the study of Roses where Parkman and Ellwanger have left the subject. The field is an inviting one. The possibilities of Rose-culture in this country are great, and so are the possibilities of improving the various races of the Rose to meet the demands of the different climatic conditions in various parts of the country. What a tempting field California and our southern States offer to the enthusiastic rosarian! There is much to learn, too, of the possibilities of Rose-culture in the trying climates of the northern States. Certainly there is not now in American horticulture any other field where careful study is so much needed as in that offered by the Rose, and no other where intelligent investigation in the right spirit will find so little competition, or can do more useful work or earn for the investigator a more agreeable reputation.

The Mandioca.

IN an economic point of view the Mandioca, or Manioc, is one of the most important agricultural productions both of Brazil and Paraguay. It takes the place of wheat in the northern continent, furnishing the inhabitants with an abundant, cheap and nutritious breadstuff, yielding an enormous quantity of material all the year round. With this the people are independent of the rest of the world for food. Here, in Paraguay, I do not know how they could get along without it. Corn, or maize, as it is generally called, is indeed raised, but it is a somewhat uncertain crop, and needs more cultivation than the native Paraguayans are disposed to give to anything which requires care. Their chief article of subsistence, therefore, is this wholesome and easily raised root, which the laziest people on earth can have with scarcely any labor.

As found here, the Mandioca is of two forms or species, each of which has several varieties. One of these, which has borne various botanical names, such as *Manihot Aipé*, *Manihot palmata*, *Jaripha Læstingii*, and *Fathropha dulcis*, but called by the Paraguayans "*Manioca dulce*," is the most common. The other, known to the natives as "*Manioca brava*" (*Manihot utilisima* of botanists), is not so frequently cultivated, though it is often seen in the fields. The sweet Mandioca forms the principal article of diet of the common people, as its roots are entirely innocuous. They may be used as a vegetable for the table, equaling the potato or parsnip, which they much resemble. Boiled for table use, they are white, sweet and palatable. All foreigners take to them at once. They may be fed to animals in the raw state, and are greedily eaten by cattle without injury. They are full of starch; indeed, that is the ingredient which renders the Mandioca so valuable, and the roots are frequently used as is the potato in our own country, for the manufacture of this important commercial and domestic necessity. The roots are grated or ground into powder, and, after the juice is expressed, dried in the sun or on plates over a fire, and thus made into flour, which forms an excellent bread when baked. The Paraguayan method is to knead the bread with new cheese or ground rice, melted fat, salt, water, and a little coriander seed, prepare it in long cylindrical rolls or rings, and bake it in the rounded earthen or brick ovens, resembling huge ant hills, which may be seen in the rear of many of the houses. The bread thus prepared is commonly called "chipa," and is, at least when fresh, a delicious article of food. The native women make and sell quantities of it in the Asuncion market. In the town of Luque, on the Asuncion and Villa Rica Railroad, they are noted for the fine bread which is made of this flour, and the passengers eagerly purchase it from the women who offer it for sale. I have also seen pastry and sponge cake made of the flour as light and palatable as anything prepared from wheat flour, and I do not know why it may not serve all the purposes for which the latter is used.

If the ground powder is heated upon iron plates and partially cooked, it clusters into hard and irregular lumps, and forms the well-known tapioca of commerce, or, prepared somewhat differently, it becomes the article known in England as "Brazilian arrow-root."

The *Mandioca brava* does not differ much from the *M. dulce* in external botanical characters. Both are stout herbs, growing from five to eight feet high, branching and very foliaceous. Both have their flowers in short axillary racemes, the flowers small, purplish white and nodding, producing a capsular, five-valved fruit, and an acrid, milky juice. The leaves of both species are alternate, on long petioles, palmate, with narrow, deeply-cut lobes. The natives, however, readily distinguish the two species. *M. dulce*, they say, when questioned, has red stems, petioles and leaves, while those of *M. brava* are white. On examination, however, it will be found that this distinction will not always hold good, as *M. dulce* frequently has stems and petioles almost or quite white, while those of *M. brava* are not unfrequently reddish. A much better distinction lies in the shape of the stems, which, in the former case, are nearly or quite terete, while in *M. brava* they are more or less angled; and also in the angle at which the petioles of the two species spring from the stems, rising in *M. dulce* at a right angle, or even sloping downward, and in *M. brava* at an angle of sixty or forty-five degrees. After all, the only satisfactory distinction lies in the juices of the two plants. That of *M. dulce*, as already stated, is sweet and innocuous. That of *M. brava*, on the contrary, is poisonous. The juice of this species has been known to kill cattle if the roots are eaten in the raw state. If, however, the juice is thoroughly squeezed out, and the grated pulp dried, it may be used in making flour and bread, like that of the other species. Indeed, some of the people here tell me that they prefer the bread made from *M. brava* to that made from *M. dulce*. It makes a lighter bread, they say, but I cannot see much difference between them. In Brazil, I believe, the *M. utilisima* is most commonly used in making cassava bread and tapioca, but either species will produce the same result, and certainly *M. dulce* is much the safer of the two. Why two species so closely resembling each other in all external botanical characteristics, growing side by side in the same soil and under the same conditions, should develop such different active principles, is one of the vegetable mysteries which cannot be solved; but that they do is certain. I do not find that the roots of the *M. brava* are ever exposed for sale in the market, though those of *M. dulce* may always be seen in great piles upon the floors and benches of the market-house. The people evidently have a wholesome dread of the poisonous species.

The *Mandioca* is very prolific. It is grown from slips, and never from seed, so far as I have observed. All one has to do in order to get a field of it is to cut the stem into layers, as is done with sugar-cane, and stick the joints into the ground, where it readily sprouts. I am told that one plant will continue to send out roots for nine or ten years in succession, and even propagate itself in this manner, if not cut off. The roots, which are the only part of the plant used, are from one to two inches thick, and run just beneath the surface of the ground for two or three feet. They have a brownish coat, and a granular, white interior. For table use they are generally taken when about nine or ten inches long, or else broken up into pieces of this length.

Thomas Morong,

In the Bulletin of the Torrey Botanical Club.

The Redwood Forest.

IN size of individual specimens, the Redwood (*Sequoia sempervirens*) ranks next to its relative, the Big-tree of the Sierra Nevada (*Sequoia gigantea*), and the Eucalyptus of Australia; but if we take the average size of the trees and the density and extent of the forest into consideration, the Redwood is the grandest of the world's forest-trees. It belongs to the Coast Range of northern California. A few straggling groves only are to be found below Monterey Bay, and it does not extend far into Oregon. The largest body commences at the mouth of Russian River and extends into Oregon. Another large forest lies south of San Francisco, in Santa Cruz County. The widest portion of the great or northern body of Redwood timber lies in Mendocino County, between Ukiah and the ocean. Here it is by air line twenty-five miles wide, a vast, unbroken forest with branches extending inward up the cañons. The peculiarity of the Redwood is its love of moisture, which means here fog. The fog banks rise from the Pacific and flow inland like a great level sea of vapor. The lower mountains next the coast are enveloped, and farther on it fills the cañons, leaving the high mountains to rise like islands out of it. Still further inland only the lower portions of the cañons are filled with fog. At times the sea of fog will rise so high that it engulfs nearly the whole section back to the high dividing range of mountains which is the watershed between the streams running directly into the ocean and those which flow into the Russian and Eel Rivers, which extend for a long distance parallel to the coast line. Then the fog goes pouring through the passes in actual rivers of vapor, which run down the cañons toward the interior. Strangely enough, it always returns as it goes.

Now, with this sea of fog in mind one can locate the Redwood belt most accurately. Near the coast on the lower mountains and everywhere, the densest forest is almost exclusively of Redwood. Farther inward sweeps the same dense forest on the lower mountains and in the cañons at the same height. Redwood forest it is still on all the mountains, but of smaller trees, and the greater the elevation the more largely it is mixed with Douglas Spruce (*Pseudotsuga taxifolia*) and the Tan Bark Oak (*Quercus densiflora*). Still farther inland near the watershed spoken of before, Redwood only grows in the cañons, and the mountains are either open grazing-land, covered with Oak and Fir, or with that dense, low growth known as Chemical (*Adenostoma fascicularis*). Over the watershed, down those cañons where the fog pours over, there still are groves of Redwood, well confined to the moist banks close to the courses of the streams; while up the broad cañons of Eel and Russian Rivers the fogs roll and nourish the life of the grandest of all of the Redwoods till they are held back by the heat of the interior.

The Redwood is not only a lover of moisture, but, to an extent hardly to be believed unless seen, a condenser and conservator of moisture. Their tops reach high into the sea of vapor, and a constant precipitation from them like rain takes place. Last summer I was on the coast during a foggy time, and I remember that while the roads were dry and dusty, in the clearings under the Redwoods the water had been precipitated till it stood in puddles and formed mud holes. This abundance of moisture causes the densest of undergrowth, which only continual fires make passable. Hazels, Huckleberries, various *Ceanothus*, Ferns of large size and in the greatest profusion, with large bushes of *Rhododendron* and numerous other plants, make the forest floor a perfect tangle in the moist portions. The list of herbaceous plants here is not large, but they are delicate and beautiful. The glossy leaves of *Vancoveria hexandra* form dense masses; an Orchid, *Goodyera Menziesii*, is common; and in the spring *Trillium ovatum* and the *Erythroniums* are plentiful and so is the lovely *Clintonia*.

Of small Ferns, only the beautiful *Adiantum pedatum*, the Maiden-hair, is common; but there are several species of *Aspidium* and the *Woodwardia*; and Brake is everywhere, making in the cleared forest a solid mass four or five feet high. I have seen acres of the Brake seven or eight feet high, where a man could only crawl through the tunnel-like paths. Every year or two forest-fires sweep through this forest-tangle, but it springs up again with renewed vigor. The Redwood, unless very young, is not injured by fire. Its thick bark protects it, and often trees will be seen which had every limb stripped by the fire putting out a mass of foliage from top to bottom. No name could be more appropriate than *Sempervirens*, for it possesses wonderful vitality. A tree cut throws up hundreds of strong sprouts, and a stump is only killed by repeated burning. Fallen trees will often grow along the whole length of the stems, and throw up sprouts from the upturned roots; and I have seen sprouts six or eight feet high from logs. The commonest care would ensure the perpetuity of these grandest of forests.

Carl Purdy.

Vegetation in Central Pennsylvania.

THE unusual mildness of the past winter, coupled with the excessive rains of the summer, have had a marked effect on many of our fruit and ornamental shrubs and trees. The poverty of bloom and general backwardness are conspicuous on every hand. The prospect for fruit is not encouraging. Cherries promise better than any of the other stone fruits, but their blossoms are thin and scattered; and one looks in vain for a single tree—even a Morello—which presents the usual resemblance to a "ball of snow." The ground underneath our finest trees is thickly strewn with the large flower-buds, each of which when opened shows the tell-tale black spot in the centre, although the scales and outer parts have enlarged a little. Peaches present a sorry sight. The older trees have either succumbed entirely, or have lost a large part of their branches, while the young trees show vigorous buds only here and there, the others having so swollen during the mild weather of January that they fell an easy prey to the few cold days of early March. The Peach is no doubt our most unreliable tree. It grows vigorously for a few years, but is strongly inclined to overbear, and unless this is checked by thinning the young fruit—which ought never to be neglected, although it generally is—it succumbs a few years later. Plums are in much better condition, but the blossoms are practically wanting.

Pears show the effect of the winter most plainly, since their large flower buds are easily distinguished, and still remain (May 7th) upon the trees, though shriveled and dying. The large-budded and vigorous growing Asiatic varieties, Mikado, Sha Tea, etc., of our Pear-orchard, are especially marked. They set fruit buds abundantly, but I do not think a single one is now living. Not speaking of the quality of the fruit, these varieties have much to commend them in their rapid growth and beautiful leaves and flowers, but the large, easily coaxed out buds must make their fruiting quite uncertain. The Apples are not yet in bloom, but they have pushed rapidly within the past few days. A considerable proportion of the trees are without flowers, and notably of such reliable kinds as the Crabs, which seldom fail. But the general outlook at present is much better than for any of the other large fruits, and favorable weather and absence from insect attack may fully make up for the scanty bloom.

Of flowering shrubs, the Forsythias, which we have been at some pains to recommend and disseminate from our nursery, present a curious sight. Instead of the profuse bloom which makes it the most conspicuous of our spring shrubs, it has only here and there a single flower, all the others having been nipped in the bud. Akebia, our prettiest twiner, held its leaves last year much longer than usual, and until the time the flower-buds generally begin to swell, but for some weeks thereafter not a sign of life was visible. Now, the first week in May, when it should be full of flowers and the delicate, five-fingered leaves rapidly expanding, there is but a hint of life at wide-scattered intervals, and latent leaf-buds are only slowly waking to the work that is thrown upon them. Early in February its flower-buds were expanded so far that the flowers could be seen. A month later they were dead. A Jackman's Clematis, somewhat sheltered, had young growth an inch and a half long. Tartarian Honeysuckles were also very forward through January and February; but they do not seem to have expended all their stock of buds, and are but little delayed, though the Honeysuckle promises but little bloom.

Naturally, everything which carries flower-buds through the winter suffered, and the larger the buds, the more easily were they deluded by the false hopes of midwinter, and the more easily they fell a prey to the cold weather of March.

New or Little Known Plants.

Buckleya distichophylla.

THE French Broad River, one of the most picturesque of the streams which have their source in the Alleghany Mountains, flows along the base of a high limestone cliff just before it passes from North Carolina into Tennessee. This is Paint Rock, on the right bank of the river, and a few miles below the Warm Springs of North Carolina, a well known and much frequented health resort. Paint Rock is divided by a small stream which cuts through it nearly at right angles with the French Broad, into which the smaller stream falls at this point, marking the boundary between the two states. On the steep rocky ledges which rise from the banks of the smaller stream, which, unless it is swollen by freshets, is hardly more than a shallow brook, grows one of the rarest plants in America—*Buckleya distichophylla*, of which the first figure which has appeared is published on page 237 of this issue.

It is an interesting feature of the flora of the southern part of eastern North America that it contains several plants extremely localized; several of them monotypic, like *Neviusia* and *Darbya*, others like *Shortia* and *Buckleya*, with east Asia representatives hardly to be distinguished from their American prototypes; and others like *Croton Alabamensis* and *Rhus cotinoides* (a true Old World type), representing widely distributed American genera, but themselves very local. Several other plants could be named were it necessary to show more conclusively the changes which time has brought about in the character of our flora, reducing the number of individuals of certain types once widely distributed, if the theory of gradual extermination of certain forms of plants is to be accepted, to a few hundred or a few thousand individuals. *Buckleya* is one of the rarest of all these plants. The only place where it is known to grow is on the steep rocky ledges of Paint Rock. Here is the last stronghold in America of a very peculiar type, which, as it still exists over a considerable area in Asia, once occupied, it is possible to conceive, a much larger space on the American continent than it does at present. But there are special reasons why this particular plant cannot spread far or very fast from any spot where it had obtained a foothold. The male and female flowers are produced on different individuals, so that fertilization might not be accomplished always easily; and the seed, which ripens and falls in September, when the ground is usually dry and unfit to secure germination, loses its vitality almost immediately by the degeneration of the oily albumen which surrounds the embryo. The branches will not root like those of many plants when they come in contact with the soil, and it does not spread by underground shoots or stolons. The propagation of *Buckleya*, therefore, is dependent on the seed finding conditions favorable to its immediate germination; and that it does so still sometimes, is shown by the fact that a few seedlings and young plants are scattered among the older individuals; but there are not a great many of these, and one fire of very moderate severity would exterminate *Buckleya distichophylla* from its native locality as completely as *Gordonia Allamaha*, another very local southern plant, has been exterminated from the only spot it is known to have inhabited naturally.

Buckleya distichophylla has been known to botanists for many years. It was discovered by Mr. Thomas Nuttall, who, returning from one of his western journeys, ascended the French Broad in the autumn of 1816, and found this plant, which he referred to the genus *Borya*. Twenty or thirty years later Paint Rock was visited by Mr. S. B. Buckley, who made many botanical explorations in the south-

ern states, and finally settled in Texas, where he died a few years ago. Dr. Torrey, to whom Buckley sent specimens, determined the true character and relationship of the plant and bestowed upon it the name it bears. Asa Gray appears to have been the next botanist to visit Paint Rock. In 1842, soon after the charge of the Cambridge Botanic Garden was entrusted to him, Dr. Gray made a long journey through the mountain region of the south for the purpose of collecting roots and seeds for the garden. His visit to Paint Rock is interesting because he brought away with him a root of *Buckleya*, which he planted at Cambridge, where it still flourishes, and which, up to two years ago, was the only individual of this plant in cultivation. For years every effort was made to propagate the Cambridge plant; it bore pistillate flowers only, and so produced no seeds; neither green nor hard wood cuttings would strike; root cuttings failed to grow; layers were unsuccessfully tried year after year; no stock could be found on which it could be grafted successfully, and the experiment of grafting pieces of the roots with the branches, the last resource generally of baffled propagators, was equally unsuccessful. So for nearly forty years the Cambridge plant remained the absolutely unique representative of this genus in cultivation, an instance of rarity of a garden plant without a parallel so far as I can remember, when the period during which it lasted is considered.

A number of botanists have visited Paint Rock of late years, but none of them were there at just the right season to secure young plants or ripe seeds of *Buckleya*; but in the autumn of 1888 Mr. Canby and I went across the Big Smoky Mountains of Tennessee, and then made a detour to the French Broad for the purpose of looking up *Buckleya*. Fortunately, we got to Paint Rock just as the ripe fruit, of which there was a great crop, was falling, and we were able to secure several hundred seeds, which were sent home at once, packed in damp soil, and also a number of small seedlings. The seed arrived at the Arboretum in good order and germinated at once. Several of the young plants which we dug up have survived, so that there is now reason to hope that the existence of *Buckleya* in America may not be dependent on the rather remote chance that the surface of the ledges of Paint Rock may escape a visit of fire, and that the single old plant in Cambridge may last indefinitely.

Mr. Faxon's drawing shows so clearly the structure of the flowers and fruit of *Buckleya*, which are described in standard works of botany, that nothing more need be said about them now. The plant grows to a height of ten or twelve feet, with slender, graceful, spreading branches, and light green, delicate foliage, which is its chief beauty, the flowers and green fruit being quite inconspicuous. It is a member of the small although widely distributed family of the *Santalaceæ*; and its North American relatives are two shrubs of the southern states, *Pyrularia*, the Oilnut, and *Darbya*; and a familiar and common herb of northern woods, *Commandra umbellata*.

Foreign Correspondence.

London Letter.

DECORATIVE PALMS.—The number of Palms now grown by nurserymen in England is surprising. They are represented by hundreds of thousands in some of the principal London establishments, and they are said to find a market readily enough to satisfy the growers. The seeds are imported by the bushel and sown, not in pans or boxes, but on beds in low houses where they require little attention and may be forked up and planted with ease. The species most abundantly grown are *Kentia Belmoreana*, *K. Fosteriana* and *K. Canterburyana*, *Areca lutescens*, *Seaforthia elegans*, *Ptychosperma Alexandra*, *Hyophorbe Verschaffeltii*, *Latania Borbonica* (*Livistona Sinensis*), *Cocos Weddelliana* and *Geonoma gracilis*. These names are those used by the nurserymen and I therefore use them in preference to those favored by botanists. An instance of the difficulties often presented by synonymy in plant names recently came under my notice. A nurseryman who grows *Latania Borbonica* by the thousand sent to Kew

for a plant of *Livistona Sinensis*, which, he said, was unknown to him. These Palms are the easiest of plants to accommodate when young; they may be grown huddled up together in a manner that would be fatal to most plants, and they grow into nice little plants in three years. They can be watered with the hose or large rose watering can, and they may safely be left to the care of a boy or garden laborer. I am informed that many of these English-grown Palms find buyers in America.

Whilst on the subject of Palms I may refer to the very interesting and instructive paper on "Exotic Palms in Florida," by Mr. T. L. Mead (see GARDEN AND FOREST, p. 175). If any one wishes to know how much or how little a knowledge of geographical botany may be expected to assist the cultivator in regard to questions of temperature he cannot do better than study Mr. Mead's report on the effects of from nine to eleven degrees of frost on the plants he enumerates. *Areca sapida*, a native of New Zealand, lost every leaf, whilst *Elæis Guiniensis* and *Raphia vinifera*, both from the equatorial

and which is in the collection of Baron Schroeder. It resembles the type in every character except color. The sepals and petals are flushed with lilac, and the reflexed portion of the labellum is colored dull bluish purple. It is more curious than beautiful. The plant appeared in the collection of Monsieur Vinck some three years ago, and it has shown the same peculiar color in its flowers every year since.

DENDROBIUM MACCARTHIE.—This magnificent plant is now flowering freely at Kew. It is one of the least common in gardens from the fact of its being bad to cultivate. It is found only in Ceylon, where it is much less plentiful now than it was a few years ago, owing, probably, to the visitations of the Orchid-collector. The Kew plants have this year made pseudo-bulbs over a yard long, and they bear near the top pendulous, three-flowered racemes, each flower being four inches across when fully expanded; the color is pale rosy mauve, with a large blotch of maroon-purple on the lower part of the lip, and streaks of the same color on the front portion. The Kew plants are grown in a very hot, moist stove,

Fig. 37.—*Buckleya distichophylla*.—See page 236.

4. Staminate flower, enlarged. 5. Vertical section of a staminate flower, enlarged. 6. Pistillate flower, enlarged. 7. Vertical section of a pistillate flower, enlarged.
8. Vertical section of a seed, somewhat enlarged. 9. Embryo, much magnified.

swamp regions of Africa, were in the one case partly cut back, in the other untouched. Two Palms from the hot, moist climate of the Sechelles—*Latania Commersoni* and *L. Lodigesii*, and *Phoenix paludosa* from the hot swamps of Bengal, were "all unhurt." *Hyophorbe Verschaffeltii* and a *Dypsis*, both from Mauritius, also escaped serious injury. These Palms are found wild only in the hottest of tropical countries, where frost would be unknown to them, yet they suffer less from frost than many plants, such as the Chilian Guava, the Cape Tecoma, Peaches, Oranges and even Roses, which when wild annually experience at least a little of it.

What are the structural or protoplasmic differences in these plants which account for this extraordinary behavior when exposed to cold? Records such as that by Mr. Mead are of the very greatest value to cultivators. We are only just beginning to get away from the notion that all plants from tropical countries must be grown in a hot-house.

BLUE-FLOWERED CATTLEYA.—The nearest approach to a blue *Cattleya* is a variety of *C. Lawrenceana* called *Vinckii*,

where they are kept saturated at all times save when the leaves are falling. It grows all through the winter, the flowers pushing immediately after the leaves have fallen.

DISA RACEMOSA.—This new and beautiful cool-house Orchid is again flowering freely at Kew. It grows and increases by means of stolons rapidly. The leaves are tufted, as in *D. grandiflora*, and the scapes are from a foot to eighteen inches high, with large, rosy red flowers. I described this plant last year, and refer to it again now so that Orchid-growers may not overlook it. In my opinion it is almost, if not quite, as good a garden plant as *D. grandiflora*.

ECHIU CALLITHYRSUM.—A tree-like example of this gigantic Bugloss is now the most attractive plant in the Winter Garden at Kew. It is twelve feet high and as much through, and almost every one of the hundred or so branches is terminated by an erect spike or thyrus of deep blue flowers, the flower-bearing portion of the strongest spike measuring a foot in length and as much in circumference. This specimen

has been gay with flowers for about three weeks, and it is still a magnificent picture. Of the many species of *Echium* found in the Canary Islands, this is much the handsomest and most satisfactory as a garden plant in England. Three years ago seeds of over thirty species of *Echium* were obtained for Kew from Teneriffe, but the plants raised from them were not worth the room they required. *E. callithyrsum* is sometimes called *E. arboreum*. It requires liberal treatment, a position where it will get plenty of sunshine, and it should be planted out, not grown in a pot. I should say that in the warmer parts of your country this species would grow and flower well in the open air.

STATICE.—Many of the species of this genus are found in the same region as the *Echiums* above mentioned, and they are exceedingly ornamental in flower when well grown. Seeds are easily procured from Teneriffe or Madeira, and plants may be grown from them in two years quite as large as large cabbages, and bearing long, branching scapes of rich blue or blue and red flowers. A few of the smaller species, such as *S. latifolia*, *S. macrophylla*, *S. profusa* and *S. Butcheri*, are grown as greenhouse plants in England. The flowers remain fresh on the plants many weeks; indeed, they are practically everlasting.

Cultural Department.

Some Notes on Echinocactus.

THE genus *Echinocactus* is represented in southern California by a great diversity of forms which nearly approach each other. The *Cactaceæ* are generally recognized as very difficult to study, not, perhaps, because they are characterless, but because of the difficulty of making specimens and the usual lack of material for study. Only by very extended and close field observation can one arrive at correct conclusions relative to species and varieties, and this none of our botanists have yet enjoyed.

Near San Diego the genus is represented by *E. viridescens*, Nutt., usually a low, depressed plant of about thirteen ribs, with pale straw-colored flowers and a slightly acid, pleasant fruit. This is a maritime species or variety almost wholly restricted to the immediate neighborhood of San Diego.

Echinocactus Orcuttii, Engelm., is found a little further to the south and further inland from the coast. It differs in size, the number of ribs (usually twenty-two to thirty), and in the young plants, which are globose. It is inclined to grow in cæspitose clumps of fifteen to twenty cylindrical heads, around which the ribs are often spirally inclined. It seems to form almost a connecting link between *E. viridescens* and *E. cylindraceus*, Engelm., which was originally collected by Dr. Parry on the eastern slopes of the mountains bordering the Colorado Desert, in San Diego County. Dr. Engelmann was at one time inclined to doubt its right to specific rank, as other botanists are still inclined to doubt. In 1882 I found what I determined was this species in the desert cañons of Lower California and also west of the mountains near the San Rafael Valley, and Dr. Engelmann wrote that he concurred with me in that opinion. This Cactus was a fine cylindrical plant, encompassed by a fine network of its slender, recurving white spines, with lemon-yellow flowers.

Echinocactus Lecontei, Engelm., is another species originally credited to the eastern slope of our mountains and to Arizona. Hundreds of plants annually reach the European market under this name, collected within the confines of the Colorado Desert, which differ in only a slight degree from *E. cylindraceus*. This form is more inclined to a grayish color, less flexible spines, and perhaps to a more globose shape. The demand in Europe for this particular species makes it command a higher price than many others, and it was only recently that I learned whence the trade was supplied. As they are collected near the original locality cited for it, no blame can attach to those who endeavor to supply the demand, but I must consider it merely a "trade name" for a form differing in no essential character from other plants yearly sent out under this, the preceding and the following names:

Echinocactus Wislizeni, Engelm., is the oldest name applied to any of these forms of Cacti. Some of the plants received under this name are beautiful, with white spines like those of *E. cylindraceus*; others have exceedingly handsome red spines; still others have dull spines of no special color. In young plants especially the color is very variable, as are also the spines.

Echinocactus Emoryi is the last of our Californian species to receive notice. It more nearly approaches the two first men-

tioned species, the reddish spines and flowers being usually the most characteristic features. But along with the red-spined and red-flowered plants I have found other varieties—white, green, brown and other shades—until no constant character can be found by which to distinguish between them.

English cacticulturists claim that *E. Orcuttii* is identical with the old *E. Californicus*, a name considered synonymous with *E. viridescens* by Dr. Engelmann. A great variety of plants have reached the European market under the latter name, which, considering its natural variations, is not to be wondered at.

I have carefully studied every form in southern and northern Lower California that I have been able to learn of, and I have been forced to the conclusion that only three true species exist within our limits: *E. polycephalus* (belonging to a distinct section of the genus), *E. Wislizeni* and *E. viridescens*. Under *E. Wislizeni* I would class as varieties *E. cylindraceus* and *E. Lecontei*; while under *E. viridescens* I would place *E. Emoryi* and *E. Orcuttii* as sufficiently well-marked varieties. Several other varieties of both these species could be sufficiently distinguished to satisfy the foreign trade. Perhaps these views will not be retained when I become more familiar with Arizona, New Mexico and Mexican forms, but they are certainly in line with the later views of Dr. Engelmann, the greatest authority on the family that we have had. C. R. Orcutt.

San Diego, Cal.

Chrysanthemums in Pots.—II.

PINCHING, or stopping, should be done just as it may appear necessary to get the plants bushy and even in shape. The outline of the future plant should be determined as early as July by five or six stakes, adding others as material for training develops. The leaving, or clearing away of suckers, should be regulated in the same way as pinching, and altogether in accordance with the habit of the plant. Early flowering and naturally bushy varieties, such as Hivü Fleuri, Chevalier Damage, Sachem, President Hyde, Souvenir de Mercède, Monsieur Freeman, L. Canning, and pompones generally, require but little pinching, and are, also, better for having the suckers removed. Enchantress, Neesima, Prince Alfred, Fair Maid of Guernsey, Kioto, Belle Paule, M. Delaux, Robert Bottomley and Mr. H. Cannell seem to need some suckers left if shapely specimens are desired. From careful observation I am satisfied that, for specimen plants, suckers produce just as fine flowers as the main stems. For specimen flowers it is absolutely necessary to have all suckers cleared away, and to develop, if possible, the crown-bud at the second break rather than to rely upon those which come away from its base, which are the shoots to produce flowers on a specimen plant.

As soon as the roots are well developed, so that they interlace around the sides of the pots, which should be some time in July, I commence giving liquid manure. I have a hundred-gallon cask partly sunken, which is kept about full of water, and from which I use all the time. At first once in two weeks, and later once a week, I pulverize about two bushels of cow-manure, which is allowed to settle, and the clear top-water used. Just before using I settle every day the ferment which has risen to the surface with a stream of water, and in about a week there is very little trace of solid manure left. For a change, a pail of wood-ashes, a lump of lime or two or three pounds of guano may be added to the mixture. After housing, I gradually diminish the strength of the application until the plants are in bloom, when clear water only is used.

Disbudding should be begun as soon as the superfluous buds can be handled. It is important to concentrate at once all the flower-producing energies of the plants on just the flowers needed to fill out the specimen; but if the "chinch" bug gets at work the best laid plans will avail nothing. I have never heard of an effective remedy against this destructive insect. Disbudding is a work which requires care and skill. If the plants are well filled out—as in the case of such reliable varieties as Golden Band, Minnie Miller, Puritan, Empress of Japan, Hivü Fleuri, Chevalier Damage, Norum Bega, L. Canning, Moonlight and President Hyde—all but the terminal bud may be removed. With some others—such as Robert Bottomley, Mr. H. Cannell, M. Delaux, occasionally, and Fair Maid of Guernsey—for the sake of filling out the specimen, the terminal bud has to be removed, and two or three buds below it allowed to develop.

I prefer to house the plant at the first danger of frost rather than run any risk from chills. A light, airy greenhouse is better than a pit, although I have had some plants do well enough in a pit where they were set up on pots so as to come

The Greendale Oak.—See page 233.

as near the glass as possible. I take the sashes off whenever the weather permits. For mildew I know of no remedy except sulphur, and I use black sulphur for look's sake. To air evenly is the best way to guard against mildew.

If the hose is applied at every favorable opportunity there is little danger of the different kinds of Aphis getting a foothold; except, possibly, the black variety. Dalmatian powder or Tobacco-dust is generally a sufficient remedy. After housing a small, reddish brown, hairless caterpillar (or what seemed to me to resemble a small cut-worm) eat the centres of the flowers. Being scarcely thicker than an ordi-

nary knitting needle and only one-third of an inch long, it was some time before I found these pests secreted amongst a few curled up dead leaves at the base of the plants. The stock plants were stored away until time for taking cuttings, which were placed in an ordinary cutting-bed, when some of the same enemies began to work on them, and gave me enough to do to keep them down. Their numbers increased rapidly, and spread on many other plants. Professor Smith, of the New Jersey Agricultural College, informs me that the pest is the larvæ of some nocturnal moth.

Roses under Glass.

THE in-door Rose season being now practically over, a few brief notes on the successes and disappointments of the past winter may be of interest. From a Rose-grower's point of view the winter was a trying one, although the temperature was not low; nevertheless, long-continued dull weather and an atmosphere saturated with moisture made careful watching necessary. Some growers attained success, but many others were unable to prevent the gradual depreciation of their stock and were forced to admit that the problem was too deep for them. The disease known among growers as "yellows" was a frequent cause of failure, and, as usual, various opinions were expressed as to its cause and prevention; but it still appears the most reasonable view that the disease is caused by an excess of moisture, either at the root or in the atmosphere, and it is aggravated by too high a temperature at night. It is only fair to state, however, that this opinion is not universally held.

The maintenance of a regular and proper temperature in the Rose-houses has been a matter of considerable difficulty, because the changes of weather have been so frequent that, without the presence of a reliable night-watchman, it was almost impossible to predict the condition of a house over night. This extremely variable weather has, perhaps, been less trying in those establishments where the heating is done by steam, as it is, doubtless, much easier to increase or to reduce the temperature of a house thus heated (provided the house is properly piped) than in one heated by hot water. It may be added, however, that all the good Roses sent to market during the season were not grown by steam heat.

Fashions in roses are changeable. Red roses, for example, were in great demand for several seasons preceding the last, and this was true in New York during the last season; while in Philadelphia red roses were seldom called for, and even so uniformly popular a flower as General Jacqueminot was not sought for with much eagerness. Some good flowers of W. F. Bennett were occasionally seen, but this rose, like American Beauty, does not give entire satisfaction, and appears to require some peculiarities in soil and treatment that are not generally understood.

The Duchess of Albany when first offered took the popular fancy, and found a ready sale, though it is claimed that this rose does not retain the brightness of its coloring after being cut for a time, and if this be proved true it is very doubtful if it will be able to usurp the place of La France. But as the Duchess of Albany has proved a profitable flower during the past winter, it undoubtedly will be largely planted next season, and a thorough comparative test will be given to it. Madame Hoste is established in popular favor, and seems destined to become a standard sort for forcing. Its large buds are of beautiful form, though not very distinct in color, and while it does not make an extra strong growth, it is free flowering, and appears to have a good constitution.

Souvenir of Wootton has created some disappointment, due in a measure to the fact that it was over-rated at the outset, and therefore aroused too high expectations. It is a good grower and a continuous bloomer, and the color is bright and pleasing. It is claimed that some flowers of this variety were produced as large as those of American Beauty, but it was not my good fortune to see them.

Ernest Metz is a Tea Rose, much commended by some growers, and it produces large and handsome pink flowers of good form. It has not been grown largely as yet, but as there are already so many good pink Tea Roses for winter flowering, a new-comer must develop many good qualities to secure a place on the list.

Among Hybrid Perpetuals for forcing there have been few innovations. For early work Anna Alexieff, Anna de Diesbach, Magna Charta and Mrs. John Laing are most prominent. Ulrich Brunner has proved its qualities of color and form, but whether it is sufficiently free-blooming for commercial work remains to be seen.

Captain Christy, when well-grown, is a magnificent rose, but it is seldom seen in quantity, being considered rather shy in blooming. Baroness Rothschild, Merveille de Lyons and Madame Gabriel Luizet especially have all been seen in good condition. Mdle. Marie Cointet has been tested as a forcing Rose, but did not prove a success, the flowers failing to open properly. Emperor of Morocco, an old Rose, has been forced on a small scale this winter, but while it is a handsome flower it is too dark in color to become very popular, as there is but little demand for very dark roses at any time.

Notes on American Plants.

THE Calendine Poppy (*Stylophorum diphyllum*) is now in full bloom. Its dense masses of foliage are of a light green shade, a foot or more high, among which the numerous bright yellow flowers, often two inches wide, are displayed in fine contrast. It is a plant one would notice from a distance, and especially at this season, for its abundance of foliage. A fine and rich soil in open sunlight is what it likes.

Cardamine rhomboidea, var. *purpurea* (Spring Cress), is a charming little plant, about six inches high, which flowers about the same time as the Spring Beauties, and somewhat resembles them in the color of its flowers. They are borne in a cyme and are rose-purple, lasting a week or more. Its natural home is said to be in rich soil along streams from western New York and Pennsylvania to Wisconsin. It certainly deserves a place in every collection of American plants.

It is interesting to note the difference in the flowers of the white variety of the purple Trillium (*T. erectum*, var. *album*) from different localities. We get from Pennsylvania the true var. *Album*, with pure white flowers, as white as those of *T. grandiflorum*. Indeed, a casual observer would take them for the flowers of that plant. From Connecticut we get another form of this variety, which is intermediate between the pure white and the typical *T. erectum*. In the Connecticut form the petals are of a yellowish shade, with a sprinkling of purple. Both forms of the variety and the true purple type all flowering together make an interesting display of this species.

Heuchera Americana (common Alum-root), when stimulated by cultivation, is a valuable plant for its foliage. The root-leaves, which endure through the winter, are often over two inches wide, of a velvety appearance above, and somewhat variegated. This variegation is not so intense, of course, as in many greenhouse plants grown for this reason, but is sufficiently strong to make the leaf very beautiful, and at no season more conspicuous than in early spring, as soon as the snow disappears, precisely the time when they would be most appreciated. Later in June, when the long scape has developed its loose panicle of pretty greenish purple flowers, and at a time when it has its greatest number of rivals, it is even then an attractive plant, and its flowers are useful for cutting. Its natural home is in rocky woodlands, and it is, no doubt, a valuable plant for rockeries. Yet it can be grown in any light rich soil in shade or sun. It is, however, probable that a partly shaded situation suits it best.

Jeffersonia diphylla (Twin-leaf, also called Rheumatism-root) is now in flower. Its height is only six or eight inches, and the single white flower, about an inch wide, is of short life and endures about as long as that of a Tigridia. The leaves are on long stems from the root and are curiously separated into two parts. It is an interesting plant for collections. It needs a rich soil and prefers shade.

Hardy Plants for Cut Flowers.—IV.

THE flowers of herbaceous plants often need some additional foliage as a setting to display them to the best advantage. *Ferula communis* is a noble plant, both for the back row of the border and for cutting purposes; the leaves are beautifully divided, of a bright, shining green color, and when the plants get well established are twelve to eighteen inches wide, and are invaluable for arranging with cut flowers. *Gypsophila paniculata* is another plant that is also most useful. The individual flowers are small and inconspicuous, but they are produced on many-branched panicles, which gives them the appearance of fine mist, and when mingled with other flowers in a vase make a charming effect. The Gillenias are pretty native plants that blend well with flowers when cut. Their pretty white flowers are not large, but are borne on a much-branched stem and last a long time. There are two species, *G. trifoliata* and *G. stipulacea*, the one flowering just after the other has done, so that their flowers may be had for several weeks in summer. They should be grown by all who wish useful plants to cut from.

The herbaceous Pæonies are general favorites, the newer varieties many of them are very fragrant, the colors are beautifully blended and are very showy where large effects are needed. It has recently been stated that Pæonies take three years to flower after being moved, but this statement is misleading. Our plants, which include some eighty varieties, were all moved and divided last year in April, and most of them flowered in May and June. It is sometimes said to be best to move Pæonies in fall. This is also open to question, for when shifted at that time they are very liable to be lifted

by the action of frost and their buds injured, in which case they certainly would not flower. If planted in spring before growth commences they will flower just as well, if the operation is carefully performed without injuring the large, tuberous roots.

Pæonies are useful for their flowers and for the large leathery foliage which stands well when cut, but care must be taken not to rob the plants of too many leaves or it will weaken them considerably. *Valeriana officinalis* is an old-fashioned garden plant, with flowers more fragrant than showy. It is very desirable, and does best when divided and replanted early in spring, for with our old plants are liable to die out. *Thermopsis Caroliniana* is attracting some attention as a new plant; there is really nothing new about it, for it has been offered for sale for eight years or more. It is desirable among tall-growing plants for its spikes of yellow Lupine-like flowers. They last a considerable time in water after being cut. The plant is perfectly hardy, but does not like to be disturbed when once planted. *Thermopsis*, in common with all leguminous plants, should be left undisturbed, because the roots are few and far spreading. The Everlasting Peas, *Lathyrus latifolius* and the white variety, are also impatient of disturbance, owing to the size and length of their roots; but for cutting they are always useful, especially the white variety. These Peas may be planted near fences or screens, and, as they grow rapidly during the summer months, they make a pretty drapery for such places. *Lathyrus grandiflorus* is also desirable, owing to the size of the flowers, which are more than twice as large as those of *L. latifolius*, though there are always fewer of them on a stem. If the Californian *L. splendens* proves hardy in the east it will be an acquisition to gardens.

Passaic, N. J.

E. O. Orpet.

The Bulb Border.—Now that the Tulips are showing their gay colors, it seems a good time to note that while formal planting may be very well in the parks and on large estates where masses of vivid color are a mere item in the landscape, it does not seem to be quite in the best taste for small gardens, where everything is closely under the eye. One often sees in small gardens the Tulips ranged exactly like the picture in the dealers' catalogues, rising from bare earth in mathematical precision at exactly so many inches apart, and almost smiting one in the face by their glare. Fortunately it is only a brief display; blooming together, they disappear soon with unanimity, and are pulled out unripened, to take their chances in some out-of-the-way corner. A much more satisfactory way for the small grower would seem to be to study his surroundings and secure as long a season of bloom as possible; never any great glare, but a long succession of flowers, with an almost daily change in the appearance of the border, which while perhaps not so impressive to passers by, is more pleasing to one fond of his garden. One can secure numerous varieties of Tulips which bloom at various times during quite two months without going beyond the cheaper sorts which are offered at such a reasonable price every fall. Selections should be made of all the sections—earliest, late, by-blooms, bizarras, parrots, etc.—and it is a very good plan to mix them up so that there will be no tendency to produce effects while planting. If one fancies a mass of some one color, a lot of this may be selected to make a special clump, but the main lot should be planted irregularly, to bloom without formality. Such a bed at first will lack foliage, and it is not until the ground is fairly full of bulbs that there will be a sufficient foil of green to be fully satisfactory, so that it is well to cover the bare earth with some creeper. *Lysimachia nummularia* (Moneywort) with me is very satisfactory for such a purpose, though the commonest of garden plants, being hardy, a free grower and having pleasing foliage; while the foliage of the bulbs is ripening the *Lysimachia* is a mass of bright yellow bloom, giving color to the border, after which the creeping stems being cut out and decaying foliage removed, the border may be planted over with Tuberous Begonias or some other suitable plants. Such a bed need not be occupied solely with Tulips; clumps of Narcissi make pleasing additions—in the front breadth may be grown such early flowering bulbs as Snowdrop, Crocus, Squills, Winter Aconite, Dwarf Irises, etc.—and it is well to reserve a space as a back border where some tall growing herbaceous plants may be flowered. Canterbury Bells are attractive in such a position. If a fence borders the bed a background may be made of some good climber. For a low fence I know of nothing neater than *Vitis heterophylla*, a beautiful foliaged vine, whose sprays are very useful for cutting.

Androsace sarmentosa is now showing its rosettes of rosy pink flowers, and is a very attractive dwarf plant for the front

border or rockery, where it should have good drainage and protection from excessive moisture. It is a Himalayan plant. *A. coronopifolia* is a neat little Russian biennial which has formed a colony on the border from self-sown seeds. It forms small neat rosettes of narrow foliage, and small, white flowers are produced on short scapes. A colony of this in bloom is graceful and pleasing, and well worth growing in the spring garden. It is perfectly hardy, and much better left without protection than grown in a frame, where it is likely to become drawn.

Ranunculus fumariæfolius is a neat, Fumitory-leaved Buttercup, and its plentiful yellow double flowers, about an inch in diameter, on single-flowered scapes, are now very attractive. Golden-yellow flowers are especially welcome in the border in the early spring.

Gold-laced Polyantheses have made such rich masses of color that, although a short time since I gave the preference to Hybrid Primulas, I am tempted to say that these many flowered Primulas should have a place in every garden also. Besides being rich in color, they have the advantage of long peduncles, and thus are useful for cutting. It is rather odd that the commercial florists who furnish the salesroom and stands with so many plants in the spring do not add good strains of Primulas to their list. They are universally appreciated and probably would find a ready sale.

Aquilegia flabellata is the first Columbine to show flower this season. This is a comparatively new Japanese variety, with broad wedge or fan-like foliage. It is robust and dwarf, the flower scapes, which are radical, being about a foot high. The flowers are fair-sized, with short, hooked spurs, and in color a creamy, slightly greenish white—no trace of other color appears on my flowers, though they are sometimes said to be flushed with violet. The scapes are furnished with from three to four flowers, which are of good substance, but are not as graceful in appearance as good forms of the American Columbines. This species is said to be allied to *A. Sibirica*.

Myosotis alpestris Victoria is a very dwarf, compact Forget-me-not, which in my garden is reliably hardy without protection and excellent for borders. Like the rest of the family, it may readily be had from seed and is increased rapidly by division. Any taste may be satisfied among the numerous varieties of *Myosotis*, *M. dissitiflora* probably being the most popular species now grown.

G.
Elizabeth, N. J.

Gathering Asparagus.—In an address before the Michigan Horticultural Society Mr. Charles W. Garfield objects to the use of the knife in the Asparagus-bed, and favors the breaking off of the stems as far below the surface of the ground as they will snap easily. The same advice has been given in these columns more than once. The white underground portion of the stalk is woody and useless, and the knife, unless it is in very careful hands, is likely to injure other buds. It is also good practice to cut every shoot in the bed, large and small. Some gardeners leave the slender shoots, under the impression that the roots will thus be strengthened and bear thick stalks next year. But for some reason this result does not follow. Perhaps some roots invariably bear small shoots, and if so, they should not be favored at the expense of better plants. When all the shoots are cut the strong roots with large stalks have an even chance and overshadow and crowd out the weaker ones.

Forestry in North America.—II.

Part I. of the volume before us treats of the utility of forests, which the author shows to be twofold. In the first instance, forests are useful indirectly, in influencing the climate, in the distribution of rain-water, in the preservation of the soil on sloping ground, in the binding of moving sands and in affording shelter against winds. All these matters are exhaustively treated. In regard to the climatic influence of forests, the author gives an accurate and most useful summary of the researches which have been made to determine the effect of forest-growth upon the temperature of air and soil, rainfall, humidity and evaporation in Germany, Switzerland and France, mainly by the establishment of parallel stations, one being situated inside a fully stocked wood, and the other at some distance in the adjoining open country.

To illustrate the effect of forest-growth in protecting loose soil on hill-sides, the author mentions the Siwalik Hills, in

India, at the foot of the north-west Himalaya. We quote his words:

"Any one who has ever stood on the hills behind Hushiar-pur, in the Punjab, and looked down upon the plain stretched out toward the south-west, has carried away an impression which he is not likely to forget. In that part the Siwalik range consists of an exceedingly friable rock, looking almost like sand baked together. Formerly, the range was covered with a growth of forest-vegetation, but a number of years ago cattle owners settled in it, and under the combined attacks of man, cows, sheep and goats, the natural growth disappeared, while the tread of the beasts tended to loosen the soil. The annual monsoon rains, though not heavy, soon commenced a process of erosion and of carrying away the surface soil. Gradually, small and then large ravines and torrents were formed, which have torn the hill range into the most fantastic shapes, while the debris has been carried into the plains, forming, commencing at the places where the torrents emerge into the plain, fan-shaped accumulations of sand which reach for miles into the plain and which have already covered and rendered sterile extensive areas of formerly fertile fields. Indeed, one of these currents or drifts of sand has actually carried away a portion of the town of Hushiarpur. The evil has by no means reached its maximum extent, and if curative measures are not adopted at an early date, the progress of transporting the hill range into the plain will go on, until the greater part of the fertile plain stretching away from its foot has been rendered sterile."

The author might have added the denuded hills, and the rivers, formerly navigable, but now silted up in the Ratnagiri district of western India, and other similar instances, the counterpart of which is probably not wanting in the drier districts of North America.

Secondly, forests are useful, inasmuch as they furnish timber and other forest-produce. Under this head the author touches upon a question which will be more fully dealt with in a subsequent volume under the financial aspects of forest-management, namely, the relation of the income derived from a forest to the capital value of that forest. By way of illustration the author gives an account of the yield of a Scotch Pine-forest in England on soil of different quality and managed under different lengths of rotation. The capital value of such a property on the best quality of land, if managed on a rotation of 100 years, is stated to amount to £25 per acre for the land and £80 for the growing stock on it, total £105 per acre. Those compartments or portions of the forest on which the timber had attained the age of 100 years would contain 8,390 cubic feet of timber per acre. On the younger portions the growing stock would be less, and the estimated value (£80) is that of the timber standing on all compartments, old and young, calculated per acre all round. In the case of an estate of 1,000 acres the capital value of such a wood would be £105,000. If managed so as to furnish a regular annual yield, such an estate would produce (in the shape of final and intermediate cuttings) per acre per annum 129 cubic feet of timber, estimated to be worth forty-three shillings. Allowing two shillings per acre per annum all round for current expenses, the net income of the estate would amount to £2,050 a year, and this only corresponds to an interest on the capital value of the property of 1.95 per cent. In other words, if the proprietor sold the estate, the land with the timber standing on it, at the estimated rate, he would realize a sum of £105,000, which, if invested at four per cent. in government securities, or in other safe investments, would give him an annual income of £4,200, in the place of £2,050, which the management of the forest would yield. At first sight, therefore, forestry would seem to be a very bad business financially. But there is another side to the question. The proprietor, if he keeps his estate and manages it well, has a good chance of increasing its value. First of all, the soil of a well stocked forest improves steadily and hence the annual yield of such a forest goes on increasing. This steady improvement of land which has been kept continuously under well cared forest and the consequent increase of its timber yield is of great importance. The annual yield per acre of the state forests of the Kingdom of Württemberg (present area, 476,000 acres) has risen steadily, apart from fluctuations, from thirty-nine cubic feet per acre in the ten years 1823-32 to sixty-one cubic feet in the ten years from 1878 to 1887. Further, it is probable that in America the price of timber, and probably also in many cases the selling rate of the land, will rise very considerably. This chance of augmenting the capital value of his property and of increasing his income the proprietor loses when he sells the forest with the timber on it. On the other hand, it may be taken as certain that the interest of government securities will go down, and that it will

not in future be possible to invest large amounts safely at four per cent. Lastly, forest-property has this advantage, that if for any special purpose the proprietor requires money, he can obtain it by making extraordinary cuttings without trenching upon his capital and without necessarily diminishing the productive powers of his forest.

In places where small timber finds a ready sale, a shorter rotation, say of fifty years, may be adopted, which means that the timber is cut when about fifty years old. In that case the capital value of the estate would, in the particular instance selected, amount only to £51 an acre (land £25, growing stock £26) with a net annual income of 28-2=26 shillings an acre. In this case the growing stock of those compartments which had attained the age of fifty years would amount to 5,060 cubic feet of timber per acre. On 1,000 acres the capital value of an estate of 1,000 acres thus managed would be £51,000, and the net annual income £1,300, corresponding to interest at the rate of 2.55 per cent. These figures show that under certain circumstances it may be more profitable to work a forest on a shorter rotation. Thus the forests of Spruce and Scotch Pine in the district of Aix-la-Chapelle and other districts of Rhenish Prussia are worked on a rotation of fifty or sixty years, because the coal and other mines in those districts require large quantities of pit-props and other small timber, which gives a ready market for timber of the smaller sizes. And this holds good whether the forests belong to private proprietors, to towns or villages or to the state. On the other hand, the high forests of Oak and Beech in those districts are worked on a longer rotation, because of these kinds the large timber sells best. The state forests of the kingdom of Saxony are mostly worked on a rotation of eighty years, because they chiefly consist of Spruce, which timber in those parts commands a ready market at that age. These forests, which are managed on a very perfect system, comprise an aggregate area of 415,200 acres, and furnished in 1888 a net revenue of £392,270. The capital value of these estates (land and growing stock) is determined from time to time with great care, and it amounted in 1888 to £36 per acre, good and bad, and on this the net revenue of the year amounted to 2.62 per cent. There are, however, among the 110 forest-ranges of these state-forests a good many in which the net revenue of 1888 represented a higher percentage on the present capital value, in some instances more than four per cent.

It was right at the outset prominently to draw attention to these facts, because at first sight they seem to constitute an insuperable obstacle to the introduction of systematic forest-management in the United States. And yet it is probable that in North America the financial results of forestry will be in favor of systematic forest-management. Definite data are not available, and the following remarks are put forward merely by way of illustration. On a map in Professor Sargent's excellent report on the forests of North America, published in 1884, which represents a portion of California, and shows the distribution of the Redwood-forests, a considerable area is marked as containing standing Redwood averaging 200,000 feet (16,660 cubic feet) to the acre. These figures, it is presumed, relate to 1880, but it appears from data communicated by Dr. Mayr that at the time of his visit a few years ago the Redwood forests of California still contained some very heavily timbered lands. On page 267 of his book he gives a graphic description of some untouched woods 700 years old, the trees 275 feet high, and fifty-six stems to the acre, which contained, according to his measurements, the stupendous quantity of 188,000 cubic feet of timber per acre. Very likely, therefore, there are considerable areas of old Redwood-forest left containing much more than 16,660 cubic feet of timber per acre. Assuming, for the sake of argument, that this timber on the spot was worth twenty cents per cubic foot, the value of the standing crop would be \$3,330 per acre. Now, if a proprietor of, say, 1,000 acres of such forest were to clear the timber, without regard to the maintenance of the forest, and if he were to place the proceeds at four per cent., he would realize an annual income of \$133,000. If he were to manage the forest in a regular manner, with the view of maintaining it in a good state of productiveness, he might expect, judging from the analogy of forests in Europe, to realize a net income of two and a half per cent. on the value of the growing stock, and this would only be \$83,000 a year. As land in the case here selected would probably not be salable, its value has here been omitted. It is, however, a question whether the proprietor could at once dispose of \$3,330,000 worth of Redwood without lowering the price. If his estate contained 10,000 acres he would certainly have to be satisfied with considerably lower rates in order to complete the transaction at once. It is most probable that he would find it to his advantage to clear the

forest gradually, and in that case it would be far more advantageous at once to undertake a systematic treatment of the forest with the view of obtaining from it a steady annual yield of timber. Apart from the advantages of such a proceeding, which have already been indicated, others will suggest themselves to every practical man who has had experience in timber business on a large scale. It is more economical in the long run to make permanent arrangements for the carriage of timber by land and by water, to build roads, railways, open up streams for floating, than to make temporary arrangements which go to rack and ruin when the forest has been cleared. In a forest worked permanently upon a regular system it may be possible to settle colonies of laborers so as always to have a sufficiently large body of men trained to the work and experienced in it. And in any case the steady and systematic working of a large forest-estate will give the proprietor the benefit of the rise in timber prices which may with certainty be expected to occur in North America.

From Dr. Mayr's book, and from other sources, we know that some of the more important North American timber-trees have an extremely rapid growth. He describes a forest of the Douglas Fir in south Oregon, second growth, eighty years old, the trees 130 feet high, and 320 trees to the acre, which, according to his measurements, contained 58,000 cubic feet of timber. This means that in this forest during the eighty years of its life, on an average, 725 cubic feet were produced annually on one acre. The best Spruce-forests in Germany only accomplish about one-fifth part of this growth. Rapid growth means a large annual yield of timber and a large net income from the forest. It is not impossible that in many forest-districts of North America the financial results of systematic forest-management will be found to be far more favorable than they are in Germany. But in order to reap the benefit of these exceedingly favorable conditions the goose which lays the golden eggs must not be killed.

The remarks made up to this point chiefly relate to matters discussed by Dr. Schlich in the first or general part of his book. Another article will be devoted to the second part of the book, in which the principles of silviculture are set forth.

The Decorative Use of Flowers.

To the Editor of GARDEN AND FOREST:

Sir.—The article by Mrs. Wheeler, in GARDEN AND FOREST for January 22d, was so full of suggestion that I venture to supplement it by a few additional thoughts on this fascinating branch of decorative art. It is evident that the use of flowers is increasing, and although some persons are inclined to condemn the extravagance which selects flowers on account of their costliness rather than in accordance with their genuine beauty, it is well to remember that a more harmless kind of luxury could not be chosen.

The true artist in flowers is as truly an educator as the painter, and the crowds which always gather about the best floral arrangements when exhibited testify to the interest they arouse. The designers are rare who meet with the highest success, even in simple attempts—which, by the way, are often the most satisfactory. The art which conceals itself under the guise of simplicity and the power to adapt natural grace and beauty to decorative use are rare gifts. One worker will arrange his Laurel branches so that the curving leaves and little branchlets will present all their native charm, while another will have them bunched and twisted until the beauty of color alone remains. An Ivy screen can have every leaf naturally placed so as to form a perfect background, or the leaves may be inverted and pointing in all directions so as to annoy a lover of beauty as discords do the lovers of music. A not uncommon fault in arrangements of Orchids is that the flowers are upside down.

Skill in choosing suitable materials and making the most of them comes with practice and observation only. All of us who have tried it know how perishable and hard to manage are the fronds of the Maiden-hair Ferns. One of the florists of this city first overcame the difficulty by starting his baskets of flowers with a pot of growing *Adiantum Farleyense* and filling other things about it. The Fern, on its own roots, long preserved its freshness and natural grace of growth and motion.

It is true that an appreciation of form depends upon a more cultivated intelligence than does that of color, and yet the latter is more dependent upon accessories than form is. Light and backgrounds are essential to color, yet we have all en-

joyed the waving forms of trees in a dim light, or their graceful branches and large leaves in churches or halls so dark as to appear gloomy. Nothing gives more spirit to a combination than the radiating forms of leaves.

It is often said that green gives freshness and white brilliancy, and both can be used freely. Another principle is that while all colors look well massed by themselves, the powerful ones should be sparingly employed in combination, while the delicate and light colored ones gain by proximity and massing. For instance, a quantity of scarlet *Salvia* or *Geranium*, in combination with other reds or purples, will, at the best, appear crude and glaring; but scatter the flowers and have fewer of them mingled with plenty of white and green, and they reveal all their brilliancy. Carnations mass well, and also appear beautiful when seen singly; but Roses, with few exceptions, should show their individuality.

Concerning backgrounds, it is well to note that while nearly all feel their influence few of us think where it comes from. Color is intensified or dulled, concealed or brought out, by their use and form. Dark flowers on light backgrounds, and light on dark, are of course effective, but for our purpose we can change either of them by light colored foliage or that which gives us deep shadows. White flowers can be made beautiful even against a background of their own color by mingling dark foliage with them. Dull reds often enhance the pinks and scarlets, and maroon will sometimes make a dull purple look clear, but these are difficult effects to obtain, and better ones are easily had.

Some of our best decorators owe their success to judgment in selecting floral materials suited to the scenes they are required to adorn, as well as to skill in arranging them. When we buy flowers we can in a measure get those that meet our artistic requirements, but the supply from our own places is often limited, and so on occasion it may be well to prepare the surroundings somewhat before arranging the flowers. The more unobtrusively this is done the happier the result. A vase of yellow Lilies can be helped by being placed upon a stand covered with a blue cloth or having a blue tile top, but a curtain hung behind it of unusual color in some familiar place is likely to be obtrusive. Unusual occasions, however, demand even extraordinary decorations.

Long-stemmed flowers in suitable receptacles are likely to remain the best means of general decoration for a long time to come. Plenty of water preserves their freshness, and the flowers are usually displayed in an effective and natural position. The flower-holders offer us a way for the artistic introduction of color often wanted for the completion of the scene. With the exception of those of clear glass, which allow the stems to be seen, earthen ware in plain colors seems the best. Silver is beautiful and brass often has the effect a frame does on a picture. A dark blue, which is a rare color among flowers, can be introduced in this manner, and is perhaps the most useful color. A deep orange is another color that combines well with many things. Both these are effective in a composition where foliage and growing plants alone are in use. White is usually too glaring and hurts flowers, but there is no color that cannot be effective in some situations. Black is sometimes invaluable. One of our best known florist's workers is fond of repeating the color of his jars in the mass of flowers he fills them with, at times using them of lighter and again of darker tones of color, both being effective.

If we do not attempt anything more elaborate than these examples and restrict ourselves to the use of a few colors, success is likely to be won, although elaborate compositions need not be against the laws of art or canons of taste. An effect that pleases when it can be attained is to repeat the same color in different kinds of flowers, in which case the hue must be exact unless we intend to have shaded effects. Another is to repeat different colors in the same kind of flowers. If we have pink Roses and white ones to arrange in two vases, it is better to have one all white and one all pink, if placed where both are seen at once, rather than mingle the colors so that both arrangements are alike.

Mountainville, N. Y.

John De Wolf.

Notes.

Achillea argentea really has the silvery leaves its name implies. It seems to be the earliest of the family to bloom, and its white flowers above the neat dwarf foliage are very pleasing.

Wallflowers which were left outside all winter are much more stocky, and came into bloom earlier than those in frames. This might not prove the case in more severe seasons.

Mr. Walker, the largest grower of Daffodils for market in England, states that the flowers should be cut while in bud and be opened in water and heat under glass. As a rule, the buds should be free of the spathe before they are cut, and the very best time for cutting is just as the perianth segments burst open.

The fifteenth annual meeting of the American Association of Nurserymen will be held at the Park Avenue Hotel, in this city, beginning on the 4th of June and continuing for three days. An unusually attractive programme of exercises has been arranged, and papers may be expected from many of the leading authorities in the country upon horticulture, pomology and forestry.

Some years ago seeds of Russian Rhubarb were sent to the State Experiment Station at Amherst, Massachusetts, and plants raised from them matured seed. A number of plants have been produced from this home-grown seed, and the roots, it is said, have been sent out for trial by druggists. It would be interesting to know whether any reports as to the medicinal value of the roots have been made.

The proceedings of the thirty-fifth annual meeting of the Western New York Horticultural Society make a compact pamphlet of nearly 200 pages, filled with valuable suggestions for fruit-growers especially. A very full report of the meeting was given in this journal; but the pamphlet just received once more calls attention to the unusual amount of instructive matter contained in the addresses and discussions.

Southern tomatoes have been greatly interfered with by the frost, and hot-house tomatoes are in good demand at fifty cents a pound. Honey peaches from Florida, the first of the season, are selling for seventy-five cents a dozen. California cherries have just come in; Black Tartarians bring \$1.50 a box. New limes bring from fifteen to twenty cents a dozen. Fresh tamarinds are exceedingly fine. Physicians allow invalids to take them after medicines with a disagreeable taste, and they are used largely for flavoring lemonade.

The first part of the twelfth volume of the "Journal of the Royal Horticultural Society" of England has reached us. Reports of the Vegetable Conference and of the Chrysanthemum Centenary Conference, held in London last year, occupy a large proportion of the pages of this part, and contain a large amount of valuable information. The Journal is now one of the most useful of serial horticultural publications, and cannot fail to increase the taste and knowledge of cultivated plants. It is an essential addition to the library of every horticulturist and of every working botanist occupied with the study of cultivated plants.

Professor C. C. Caldwell quotes from Dr. Mueller to the effect that the sugar of the Grape is produced in the leaves; that toward the end of summer the older leaves diminish in activity and only the younger ones make sugar; that leaves some distance beyond the fruit may produce sugar for it, as may also leaves on lateral shoots springing from the fruit-bearing branch, but only when those shoots are above the fruit or close to it. Pruning by cutting off the ends of fruit-bearing branches was found injurious, and by too close pruning fruit was produced having four or five per cent. less sugar than fruit on unpruned branches.

During the past week the flowering Dogwood, the Silver-bell (*Halesia*), the Bladder-nut (*Staphylea*), the Black Haw, the Sweet Viburnum and the Judas-tree, among our native shrubs and smaller trees, have come into bloom in Central Park. The Lilacs are in full flower, and so are the Kerrias, double and single, *Exochorda*, *Rhodotypus*, *Azalea amœna*, the Hawthorns, and many kinds of *Prunus*. The most interesting among herbaceous plants which have lately come into flower are *Phlox amœna* and *P. divaricata*, *Iris pumila* and its varieties, *Houstonia* and Bird's-foot Violets. The park was never better kept and never looked more beautiful.

Amelanchier oligocarpa, of which a figure and description were published on page 245 of the first volume of GARDEN AND FOREST, proves to be a garden plant of great beauty; and the size it attains in cultivation, the vigor of its growth and the abundance of its flowers are surprising to those persons who have only seen this shrub growing in its home in our far northern forests. Specimens in the Arnold Arboretum are now nearly three feet high and three or four feet across, forming perfectly symmetrical compact bushes, which this year have been covered as with a sheet with their handsome solitary white flowers, which, however, like those of the other species of *Amelanchier*, are of short duration. This is certainly one of the most desirable of our native plants to in-

troduce into the garden, and when it is better known and its beauty recognized, it is certain to become popular.

On Monday of this week the Flower Mission of this city began the work of its twentieth year by sending great numbers of Apple-blossoms, Lilacs, Pansies, Buttercups and other flowers to the various hospitals and to the sick in tenement-houses. Fifty ladies were present on the first distribution-day, and it is hoped that still more will offer their services in future. The service required is not simply the arranging of the flowers in bouquets, but the delivery of them to the sick, who appreciate the flowers more highly when they receive them directly from the hands of the distributors. Donations of fruit as well as of flowers are requested for this beautiful charity.

In *Agricultural Science* for April, Professor C. M. Weed, of the Ohio Experiment Station, has an interesting note on the use of arsenites for the Plum curculio. Many experiments have been reported in which alternate trees were treated and the sprayed trees yielded as little sound fruit as the others. Mr. Weed points out that the remedy acts mainly by destroying adult beetles that feed on the surface of the fruit and foliage. It need not act upon the beetles when engaged in oviposition nor upon the larvæ after hatching. The beetles from unsprayed trees may deposit eggs on the fruit of sprayed trees, and beetles killed on sprayed trees will lessen the injury on the check trees. A fair test cannot therefore be made with a few trees close together. An examination of the question convinces Professor Weed, however, that in good sized orchards of Cherries, Plums and Apples the arsenites furnish a complete and practical remedy for the curculio.

The apple scab is caused, as is well known, by a parasitic fungus (*Fusicladium dendriticum*). The injury to fruit is often very great, and in neglected orchards the entire crop may prove of no value except for cider. Some careful experiments made by Professor Taft, of the Michigan Agricultural College, showed that the size of apples affected by the scab was reduced by one-tenth on an average, making a loss in bulk, not to speak of the loss in good appearance, of fully a bushel to a tree. Of various remedies tested the most effective was a spray of the so-called "Eau Celeste," somewhat diluted. The mixture is prepared by dissolving two pounds of copper sulphate in hot water in one vessel, and two and a half pounds of carbonate of soda in another. The two solutions are mixed, a pint and a half of ammonia is added, and the whole is diluted to thirty-two gallons. An orchard can be sprayed at a cost of two cents a tree, and the treatment may make the difference between success and failure of the crop.

The unequal effects of the past winter on vegetation in different parts of the country is remarkable. A correspondent describes on another page the condition of the flower-buds of many early flowering-trees in Pennsylvania. In eastern Massachusetts, where the winter was also exceptionally mild and where the thermometer fell to zero once at least during the month of March, Cherry-trees are remarkably full of flowers. The buds of Peach-trees are generally uninjured; Plum-trees are blooming abundantly; there is a great show of flowers on Pear-trees; Apple-buds are uninjured. Forsythias have all flowered as freely as usual, although the flowers have been perhaps rather smaller in size than they were last year. The Chinese Magnolias have all flowered well, although the size of the flowers was reduced by a frost of several degrees which occurred just as the buds were opening. The different *Ame-lanchiers* have been unusually full of flowers. Flowers of the Chinese and Japanese Apples are just opening and have never been more abundant. This is true of Thunberg's Barberry, the earliest of the genus to flower, and of Thunberg's *Spiræa*, the ends of the shoots of which are not more injured than usual. The flowers of *Andromeda floribunda* have never been more abundant or larger or better colored. Those of *Andromeda japonica* were entirely killed during the winter. The Japanese *Prunus pendula* lost some of its buds, and the flowers which developed have been smaller than usual; while the flower-buds of the Sweet Almond were nearly all killed. On the other hand, the Flowering Dogwood never gave a better promise of flowers than it does this year, although in the latitude of Massachusetts the buds often suffer in severe winters. It is unusual to see Lilacs so covered with flower-buds as they are this season in Massachusetts. The flowers of the Red Maple were uninjured, and the fruit is already half grown, although the late frosts destroyed the flowers of the Silver Maples or most of them. The Norway Maples have flowered profusely, as usual. Rhododendrons and Ghent Azaleas have never before in Massachusetts given such a promise of flowers as they do this spring.

The Management of our Experiment Stations.

THE Agricultural Experiment Stations recently established in the various states have been subjected to much flippant criticism by persons who have no adequate idea of their purposes and possible value. We recall one instance of a most instructive feeding experiment at one of these stations in which tests of certain food-rations were made to ascertain their comparative efficacy in the production of milk. The work in this case was in every way a suitable one for such an institution. The facts established could be at once put to practical use by dairymen, and could be made directly profitable in their business. The tests were such as dairymen could not make for themselves, because they required a technical knowledge and a habit of scientific accuracy in observation and measurement to which ordinary farmers do not pretend. Besides this the experiment required time and money which the farmer could not afford to expend and an equipment in the way of apparatus which he did not possess. Every one familiar with such subjects knows that investigations of this sort have done much to improve the dairy practice of the country and to secure a cheaper and better product. And yet the bulletin setting forth the results of the experiment spoken of was ridiculed in more than one of our great city dailies, the writers making themselves particularly merry over the fact that the cows treated were referred to, as is usual in such cases, by their names. Of course criticism like this is entirely empty, but it is annoying by its very silliness. It certainly is not pleasant for men engaged in serious, honest and useful work to find themselves mocked and jeered at and made the butt of vulgar jokes.

Quite as annoying, and almost as senseless, are the strictures of persons who expect too much of the stations. They complain because immediate answers are not given to questions which demand years of patient study. One man wonders why so much time is given to the investiga-

tion of the Sweet Potato disease, when he is anxious to know the exact effect of potash salts upon the sugar content of the grape. Another complains because all the new varieties of fruits and vegetables are not subjected to comparative tests, while a third objects to such experiments as worthless for other soils and climates than those of the station farm, and urges the officers to confine themselves to the investigation of principles which demand the oversight of men trained to scientific method, and leave minor details of practice like the testing of strawberries and tomatoes to individual growers, who are fully competent to decide such matters for themselves. Here we approach debatable ground, and the stations must be able to show not only that they are prosecuting their inquiries on the most approved methods, but that they have selected the proper subjects for investigation. They must be able, too, to state the principles which control this selection, and give the reason why their chosen field of study is made to include certain definite subjects, and why it excludes every other subject. Every competent station officer will welcome honest and kindly criticism which touches the vital principles upon which these organizations must stand or fall, and every such officer will admit that in matters of mere administration they should always be subject to closest scrutiny.

The stations can afford to overlook captious criticism, but they should be quick to profit by any warning or reproof from a friendly quarter, and the editorial article in the April number of *Agricultural Science* should, therefore, receive special consideration. The editor, who is Vice-Director of the Experiment Station of the Indiana Agricultural College, here charges or insinuates that, in many cases, the law which requires the quarterly issue of bulletins is not complied with; that in some states the appropriation for the station is expended in violation of the spirit and letter of the law; that, in certain cases, the money intended for the stations is largely expended upon the colleges; that the Director of one or more stations is a mere figure-head; that the work done in some stations is only scientific in name, while in reality it is a bungling farce. Now, we cannot identify the stations at which these comments are leveled, but we should be surprised if a Congressional investigation could not make out as strong a case against many of them. Even in the states where the most intelligent interest is taken in the stations it is very difficult to secure men properly trained to do the work required. There are not enough available men of this quality in the country; and in states where little attention has been given to the aid which can be rendered by science to horticulture and to agriculture, it is not improbable that the station-work has been entrusted to very incompetent hands. And, no doubt, it is true that in some cases, where a good director has been chosen, his choice of assistants has been hampered by the interference of local statesmen, who are too often eager to seize upon any position with a salary for some dependent politician. Upon the whole, the wonder is that so many of the stations are as good as they are.

And yet they must be a great deal better than they are if they are finally to escape the charge of misusing the liberal appropriation at their disposal. In the colleges and in the stations themselves a staff of young men should be under constant training, and the excuse that it is impossible to find men competent to do the work of the stations ought not to be a valid one much longer. There is an association made up of the officers of the agricultural colleges and of the stations, and it would seem to be worth while for this body to make a searching inquiry into the condition of the institutions it represents. The shortcomings of a few stations will discredit all. And it should be remembered, too, that the stations will not satisfy the reasonable demands of the people who are taxed for their support if they simply refrain from violating law and live up to the letter of their obligations. They must prove themselves positive and efficient forces in horticultural and agricultural progress. Unless they compel

respect they are failures. They will not be pronounced successful until their bulletins are accepted as standard and authoritative in the literature of applied science.

In the closing hours of the legislative session at Albany, an effort was made to smuggle through, in the form of an Amendment to another Act, a law authorizing the construction of a straight and level speed-road through Central Park. The measure was again defeated, for this was not the first attempt to pass it; but it will surely reappear before succeeding legislatures, among the various schemes to confiscate the grounds belonging to the people in the interest of a special class. This particular project, however, is a singularly offensive one. Even if the track could be constructed without interfering with the right of entrance to the park by those who would be compelled to cross it, its purpose is simply to afford pleasure to a few rich men for a short time in the spring and in the fall. To accomplish this, these men are asking the people to pay for the devastation of the scenery of the park, which is its fundamental value—scenery which it has cost millions of money and the watchful care of long years to provide. No other attack on the park contemplates the destruction of so large a portion of its area or the introduction of so many elements that are subversive of its design and purpose. These owners of fast horses have little need of the park, even if they have any feeling for its beauties, because they are able to enjoy the sunshine of the south in winter, and the cool breezes of the Berkshire Hills or of the seaside in summer. But the city is full of people who may have less money, but who have quite as much right to the use of the park and a more refined appreciation of its value. The park should be preserved for the people, and the whole people, and not ruined in the interest of horses and their drivers, however aristocratic may be the breeding of either.

The Cork Oak.

THE Cork Oak, of which a portrait taken in Algeria appears in our illustration on page 251, produces the most valuable bark of all trees, with perhaps the exception of the Cinchona, and the money value of the world's product of cork is greater than that of the quinine it consumes. It is a native of the Mediterranean basin in northern Africa, in Corsica, Sicily, southern France and the Iberian peninsula, across which it extends to the shores of the Atlantic in Portugal and of the Bay of Biscay. It is an evergreen species very much resembling some varieties of the Ilex or Evergreen Oak of southern Europe, with ovate-oblong blunt coriaceous leaves, which are sometimes entire and sometimes sharply serrate, and downy on the lower surface. It rarely attains a greater height than twenty-five or thirty feet and trunks more than two feet in diameter are exceptional. The value of the tree is in its bark. The outer layer becomes, through annual additions on the inner surface, after the tree has attained a certain age and size, a thick, soft, homogeneous mass possessing the compressible and elastic properties upon which its economic value depends. Cork is, in a certain sense, an artificial production, as the bark naturally developed by the trees is of comparatively little value. This last is called "Virgin Cork," and is stripped from the trees when they are from fifteen to twenty years old. It is rough and woody in texture and is only valuable as a tanning material or for the coarsest kinds of rustic work. The removal, however, of the natural bark causes the development of another growth of much finer and more compact quality. This is removed every eight or ten years, the quality of cork improving with each successive stripping, and the trees continuing to live and thrive under the operation for more than a hundred years. The bark is stripped during the months of July and August. Two cuts are made around the stem, the first above the ground and the second directly under the forking of the main branches. These cuts are then connected by three or four longitudinal incisions which thus divide the bark of the whole trunk into as many divisions. Only the outer coating can be removed without destroying the tree, and the greatest care is taken therefore not to injure the inner bark. The cork is removed with the aid of the wedge-shaped handle of the tool used in making the incisions. The outer surface of the bark, as soon as it is stripped from

the trees, is scraped and cleaned, and the pieces are then flattened, heated slightly and pressed under stones on a flat surface. The heating chars the surface and closes the pores, giving to the bark what is technically called "nerve." In this state it is ready for manufacture or exportation.

The amount of cork used in the world and the number of uses for it are increasing enormously. It was not until the end of the seventeenth century that bottles were stopped with corks, although it would seem that its value for this purpose was known to the Romans, as Horace ("Odes," III, 8) speaks of

"Corticem adstrictum pice dimovebit
Amphoræ."

The available forests of Cork-trees are already relatively extensive, although hardly sufficient to supply the demands now made on them, or which as the world grows in prosperity must be made on them, for there is hardly any end to the uses for cork, and none of the substitutes for it, which have yet been tried are very satisfactory or promise to take its place to any great extent. The latest estimates of existing areas of available Cork Oak forests make their extent from 3,300,000 to 3,500,000 acres, of which about one-half, including those on its African possessions, belongs to France.*

The wood of the Cork Oak is heavy, coarse-grained, and of a yellow-brown color; it shrinks and warps badly in seasoning and decays rapidly when exposed to the action of the atmosphere. It has little value in the arts but furnishes a useful fuel and makes good charcoal. The inner bark is rich in tannin and trees too old or unfit to produce cork are cut for the sake of the inner bark.

The Cork Oak is an interesting tree to Americans, as its cultivation now seems destined to become an important industry in California, where the climate and the soil in many parts of the state are admirably suited to produce it. This is not a mere theory, as trees have been growing now for several years in California and have already produced crops of cork of excellent quality. It is probable that the tree will grow rather more rapidly in California than it does in its native country, although the quality of the soil, the exposure in which the trees are placed, local climate and the treatment which the trees receive will influence, of course, the rapidity with which the bark is developed. In Africa it is found that the trees which grow the most rapidly produce bark of the poorest quality, and that within certain limits the slower the trees grow the more valuable the product, provided the growth is not too slow, in which case the bark loses some of the elasticity which makes it valuable. The conditions which influence the development of cork are so numerous and complicated that the product of all the trees in a grove or forest can never attain the same uniformity of thickness or quality in any given time. This is so well understood in the countries where cork is grown that the best method of harvesting has been found to be to go over the forest every two or three years and remove the bark from such trees as are covered with merchantable cork and not to strip all the trees at the same time. All these matters must of course be considered in connection with planting forests of the Cork Oak in California. The planting and care of such forests in Portugal and Spain has long been an important industry, and there is no reason why they may not be made so in California, where the local consumption of cork is already enormous, although the wine industry there is hardly more than in its infancy.

We are indebted to Mr. Francis Skinner, of Boston, for the photograph from which the illustration of the Algerian tree has been made.

The Cedar of Mount Atlas.

THE classical Cedar of antiquity has, it is well known, become exceedingly rare on Mount Lebanon, where it exists, outside of the famous grove of about 350 trees, in a few remote and rarely visited stations only. There is nothing more beautiful or more venerable than the little forest of Cedars standing out dark and green on the naked and forbidding background of the high Lebanon range. Each tree, with its original and expressive aspect, seems to relate a history full of memories. But this famous grove of Cedars leaves upon the visitor a sad impression, for no one who sees it can divest himself of the idea that the venerable trees are perishing. The nine old trees are mutilated and injured less by time and the severity of the climate than by the carelessness of shepherds and pilgrims, who break off the branches and often

* "Notice sur les forêts de la Tunisie," Exposition Universelle de 1889, Tunisie. Direction des Forêts.

build fires about the trees; and, what is still more serious, young plants are not growing up, as the goats destroy them as soon as they appear.

If the student of the Bible deplores the approaching loss of these, the most touching monuments of antiquity, the botanist and the forester may find at least this consolation, that the Cedar is found on other mountain ranges, so that a speedy extermination of the race is not probable. Vast forests of the true Cedar of Lebanon exist, at an elevation of from 4,000 to 6,000 feet, on the immense masses of mountains which extend all along the coast of Cilicia. It was Kotschy who discovered and described these great forests of Cedars (see his charming work entitled "A Journey to the Taurus of Cilicia," published in 1858). In reality, the station of the Cedar on Mount Lebanon is only the most southern outpost of the species, while the centre of its distribution and its real home is in Cilicia, where it is found in the greatest abundance, and where it reproduces itself vigorously. But to really comprehend the geographical distribution of this splendid tree one must look to the western and the driest part of the Himalaya Mountains, where is found that conifer known from the time of the most ancient Indian antiquity under the name of "Deodar" or "Wood of the Gods," the *Cedrus Deodara* of botanists. It is not surprising that this wonderful plant has been mistaken for a distinct species. It is a much larger tree, and its habit, although not unlike that of the Cedar of Lebanon, differs from it in its slender young shoots and in its larger and longer cones. In the opposite direction, another tree, very much like the Cedar of Lebanon, has been discovered in the Atlas Mountains of Algeria; but in the case of this tree all its parts are smaller than those of the tree of Mount Lebanon. The more the mountain chains, which extend from the frontier of Tunis in a double rank through northern Africa to the boundary of Morocco, are explored, the more widely distributed this beautiful tree is found to be. Manetti has given to the African Cedar the name of *Cedrus Atlantica*, but a critical study of these three trees has shown Sir Joseph Hooker that they are not really three species, but simply three varieties, or rather races, of the same species, as it is principally the dimensions of individuals, and not essential differences, which distinguish them.

The race of the Himalaya, in conformity with the immensity of that mountain system, where all vegetable forms assume an extraordinary size, is the largest. The race of the Taurus and of the Lebanon occupies an intermediate position, while that of Mount Atlas is the smallest, on account of the dryness of the severe climate of the region. The remarkable dimorphism, even, which appears among trees with dark green foliage, and others with silvery gray foliage mixed together in the same wood, is found in these three stations, in the Himalaya as in the Taurus and in the mountains of Blidah. This dimorphism is known to gardeners, as it is seen frequently in cultivated plants of the three varieties now widely distributed in the gardens of southern Europe.

I had the good fortune, in a recent journey, to penetrate to the region occupied by the African Cedar and to cross it at different points, and it seems to me that it might be interesting for the readers in the New World to learn a few details of a plant of the Old World which every reader of the Bible knows and has venerated from childhood. I need not recall the fact that it is the tree celebrated by Isaiah, and by David in the Psalms, that it is the tree that Solomon used for the construction of the temple, and Ezra used to finish the second temple; the tree which David used to build his palace, and which served the Hebrews for the masts to their vessels, and for the idols which this people, so often rebellious, erected, and which attracted to them the paternal punishments of God. I will merely add, however, that there are learned and competent students who suspect, at least, that in one or the other of the references of the Bible there is room for doubt, and that they do not refer to the true Cedar, but rather to the wood of the Cypress (*Cupressus sempervirens*). Indeed the wood of this tree, which still inhabits the valleys of the Lebanon in the immediate neighborhood of the Cedars, as in the valley of Kadischa, forming there dense forests, is more valuable than that of the Cedar both for construction and for the cabinet-maker. The wood of the true Cedar is whitish, rather soft, not very durable, and not odoriferous, while that of the Cypress is very hard, durable, very resinous, and of a handsome brown color, and in every way superior to that of the other tree.

I saw the Cedar for the first time in the Atlas of Beni Salah, which forms the principal part of the chain immediately behind the pretty town of Blidah, which is surrounded as far as the eye can reach by forests of Orange-trees, whence come in the months of December and January mandarins, which are

now beginning to take the place of all other varieties of the Orange.

We ascend with the aid of mules and Arab guides behind the town during five hours—for it is necessary in order to visit the Cedars to reach an elevation of nearly 2,000 feet, while Blidah is only a few feet above the level of the sea. We pass through Arab fields surrounded with masses of Cactus (*Opuntia Ficus-Indica*) fifteen or twenty feet high, and covered with the graceful *Clematis cirrhosa*, which, in January, was in full flower. Fig-trees without leaves, the great Caroubiers (*Ceratania Siliqua*), the *Zizyphus Lotus*, and a number of shrubs with shining evergreen leaves, grow on the sides of the road, with here and there an occasional plant of *Chamærops humilis*, which is the despair of the agriculturist of the country because it is impossible to exterminate its strong roots without the aid of a dynamite cartridge. We ascend rapidly; cultivated fields come to an end, and the naked flanks of the mountains, worn by the torrents of spring and deeply gullied, begin to fatigue our animals. We encounter at 3,500 feet thick clumps of the Oak, known to the Arabs under the name of "Ballus," the *Quercus Ballota* with thick, tufted, dark gray foliage resembling that of the Live Oaks of the southern United States. The large acorns are sold in the market of Blidah. They are not bitter, although rather astringent for a cultivated taste. We soon leave these Oaks behind. Chestnut-trees, although not indigenous, grow here vigorously, as do several shrubs of Europe, like the *Ilex Aquifolium*, the *Ruscus aculeatus* and the *Prunus avium*.

A little further and we reach the Cedars, which hereafter cover all the slope with an imposing solemn forest, which we admire in silence. They are, for the most part, ancient trees many centuries old, but there are also many young trees which form impenetrable thickets. Under the old trees the ground is open and hard, resounding like iron, for it is still frozen, and here and there are patches of snow. It is impossible to imagine anything more beautiful or more touching than these great trees standing in their silent majesty. The trunks have a diameter of four and a half to six feet, springing from roots twisting about like serpents; the bark is thick, channeled, dark brown. The trunk separates generally at the height of a man into vigorous, horizontal branches. This horizontal direction of the branches is repeated to the top of the trees, so that they consist of a series of flat stages covered with thick, intense verdure, but diminishing near the top, which ends in a thin, upright leader. Upon these branches the cones appear in great quantity. They are very beautiful, of a clear brown color, and covered with drops of white resin. The cones are just ripe, although the scales are still closed. A month later they drop, leaving the central axis, which remains on the branches for a long time. The leaves are short, very close together, entirely covering the branches, dark green on both surfaces, although on certain individuals they are silvery white, the contrast of color making an effect of surprising beauty. The height of these trees is not great, the highest, I should think, not exceeding 60 to 75 feet, but solidity and strength are expressed to a supreme degree in their habit. An examination of this forest shows, to our surprise, the *Taxus baccata*, the *Cratægus Aria*, the *Euonymus latifolius*, a great Juniper probably undescribed, not unlike *Juniperus Oxycedrus*, *Quercus Mirbeckii*, an evergreen species of the eastern Atlas, but rare in this region. It is not uncommon to see immense trunks of the Cedars torn, burned and whitened, either upright or prostrate on the ground. These are the victims of lightning or of fires lighted by the Arab shepherds, who like to set fire to a great tree to warm their hands.

From the summit of Beni-Salah, which rises a little above the last Cedars, and which is covered with a thick growth of *Bupleurum spinosum*, we obtained a splendid view which will rest always engraved in our memory. About us are the rocks and the gorges of the Atlas covered with Cedars, while developing at the right and left to a prodigious distance extend the ranges of the province of Oran as far as the great pile of mountains to the east of Algiers, the Djurra, with its heavy covering of snow. To the north stretches the great undulating plain, dotted with innumerable towns and villages, known as the "Metidga," and ending in the long maritime chain surmounted with that gigantic monument called "the tomb of the Christian," but which is, in reality, the mausoleum of the dynasty of the ancient kings of Numidia, of the time of Augustus and a little earlier; beyond the beautiful Mediterranean in its blue immensity appears at a distance of more than 150 miles. But what a contrast the view to the south presents! Beyond the arid plateau of the interior is seen, under a pure sky, the immense plain of the Algerian Sahara, another sea, but a sea of sand and of stone.

There is, further west, in another part of the Atlas, a region where the Cedar forms extensive and luxurious forests. This is the Teniet-el-Had, near Affreville. The Cedars here cover nearly 10,000 acres, and ascend to nearly 6,000 feet above the sea level. In the lower part of this forest the *Callitris quadrivalvis*, called "Thuya" by the Algerians, is found. It is a charming little tree, the near relative of the Frenelas and the Widdringtonias of the southern hemisphere, which supplied the ancient Romans the precious wood called "Citrus," for which they paid fabulous prices—as much as \$50,000 for a single table, and, according to Pliny, it was the great and wise Cicero who paid it. This wood is cut from the lower part of the trunk where there are numerous excrescences, and is really beautiful. It is light rose colored, regularly marked with dark red spots which form a delicate design. The great *Pistacia Atlantica*, the *Pinus Halepensis*, the most common Pine of Algeria, are found in this forest also. Many of the Cedars have here twelve to eighteen feet circumference of trunk. One of them, known as the "Sultana," measures nearly thirty feet around the trunk. The "Sultan," which is no longer alive, had a trunk circumference of nearly thirty-five feet.

The Atlas is not the only station of this tree in Africa. Beyond the Atlas and the grand plateaus of the interior, an immense mass of mountains exists in the province of Constantine, towering above the Atlas even at a height of nearly 7,500 feet. All this immense mountain region is covered with forests of Cedars which have absolutely the effect of our Spruces of the Alps, half covered in the snows of winter. From Batna one ascends in a few hours to the centre of this region. There are, at a lower elevation, forests of *Pinus Halepensis* mixed with *Juniperus Phœnicea*, which attain here a large size. Higher up the Cedars extend in all directions, and it would require days to cross these forests. The flora of these high mountains must be beautiful in summer. We only saw the remains of that of the previous year, but were able, nevertheless, to distinguish two species of Saxifrage, and a Violet, the *Viola Munbyana*, of which the seeds are now growing in our Alpine garden. At a single place in these regions in the Babor range to the east of Bougie, at an elevation of nearly 6,000 feet, M. Cosson discovered a small forest of an *Abies* which he mistook at first for the *A. Pinsapo* of Spain. It is, however, a distinct species—the *A. Babarensis* of Cosson or the *A. Numidica* with obtuse leaves, and more closely related to *A. Cilicica* than it is to the Spanish tree. It is a species which succeeds well in the gardens of Europe, although it never grows to any size.

Bâle, Switzerland.

New or Little Known Plants.

Berberis Sieboldii.

THE Japanese Barberry, of which a figure is published on page 249, may perhaps be considered by botanists an extreme form of the common Barberry, which assumes very various aspects in the different regions over which it ranges from western Europe to Japan. From a garden point of view, however, it is abundantly distinct from all the forms of the common Barberry in cultivation, and Miquel's name of *Berberis Sieboldii* may therefore well be maintained in garden literature at least.

*Berberis Sieboldii** is, in cultivation, a stout, compact shrub, three or four feet in height, with angled branchlets covered with pale gray bark, and slender three-forked spines. The leaves have finely ciliate margins and are obovate, rounded or rarely pointed at the apex, and are gradually contracted below into short, broad petioles; they are chartaceous, becoming somewhat coriaceous at maturity, dark green and lustrous, rather paler below, two inches or more long and an inch broad. They turn in the autumn to the most brilliant shades of scarlet and orange. The flowers, with pale greenish yellow ovate petals an eighth of an inch long, are produced in racemes two and a half to three inches long, and are larger than those of the common Barberry. The fruit, which is bright scarlet at maturity, is oval or obovate and half an inch long. From the common Barberry this Japanese plant differs, therefore, principally in the ciliate margins of the leaves, which are never spinulose-dentate, except on very young seedlings; in their lustrous surface; in the bright colors

they assume in autumn; and in the rather larger, paler colored flowers and in the larger fruit. It is the most ornamental of all the Barberries of the *Vulgaris* section, and there are very few plants which equal or surpass it in the autumn color of its foliage.

Berberis Sieboldii appears to have been introduced into cultivation by Mr. Thomas Hogg, of New York, who found it near Hakodate, and who sent it to the Parsons nursery at Flushing, New York. It had previously been collected by Mr. Charles Wright, botanist of the North Pacific Exploring Expedition, at the same place. The plant has been distributed by Mr. Parsons, who sent it to the Arboretum several years ago under the name of "*Berberis Hakodate*." It is perfectly hardy, and one of the most ornamental and desirable of the Japanese shrubs which have been introduced into American gardens. C. S. S.

Cultural Department.

Notes on Shrubs.

THE Japanese Witch Hazel (*Hamamelis Japonica*) is commonly classed as spring-flowering in catalogues and general descriptions, but this season it proved a winter blooming plant, and when spring opened the pleasing yellow flowers of this shrub had been long past. It is extremely unlikely that these winter flowers will be followed by fruit.

But *Corylopsis pauciflora*, another dwarf plant of the Witch Hazel family, and also of Japanese origin, if well protected in winter, bears a profusion of flowers in the spring. It is a rare plant in cultivation in this country, and is not thoroughly hardy in all situations in the latitude of Boston; but it is well worth a little extra care and attention on account of its abundant pale yellow bell-shaped flowers, which appear in short clusters long before the leaves. At the Arboretum the first fully expanded blossoms were noted about April 17th; ten days later the plants were in fullest blooming condition, and they continued to have a pleasing and attractive appearance for a further period of ten days, or until about the end of the first week of May. The leaves begin to expand as the last flowers fade. Although flowering regularly for several years at the Arboretum, no fruit has been borne on the plants. The desirable qualities of this plant, however, cannot approach those of the Forsythias with their loads of bright yellow blossoms and large, free growing habit and thorough hardiness. Among seedling plants of the Forsythias there are sometimes slightly differing shades of yellow noticeable, a circumstance which will probably be taken advantage of by nurserymen who at present propagate the plants almost exclusively by cuttings or layers. The common, upright growing *F. viridissima* blooms fully a week later than those known under the names of *F. suspensa* and *F. Fortunei*, and, as a rule, it is not nearly so handsome and satisfying as the other species, which are better suited to those who have small grounds and space for only one Forsythia. If left unpruned a single plant of *F. suspensa* may in the course of time attain very large proportions, because the ends of the long, slender, drooping branches often take root when they reach the ground, and send up new shoots. In this way the original plant may spread over a large area and form a little forest of additional stems all about it.

Everybody has observed that the young, unfolding leaves of most trees and shrubs are of a much lighter green color than they are after they become fully expanded. The leaves of a few species and varieties appear almost yellow when they leave the buds. There is a form of the native Nine-bark (*Physocarpus opulifolius*, commonly known as *Spiraea* or *Neillia opulifolia*) which is esteemed by some people for the yellow color of its foliage, and which is often sold by nurserymen under the name of *Spiraea opulifolia aurea*. When the young leaves of this shrub are expanding they have a striking effect of yellow blossoms, and at a little distance the plants are not infrequently mistaken for Forsythias in full bloom. This yellow-leaved form of the species is sometimes met with growing wild along the banks of streams, especially northward.

There is a noticeable difference in the yellow color of the flowers of the Spice-bush (*Lindera Benzoin*) on different plants. The stamens and pistils are usually produced in separate flowers, and these staminate and pistillate flowers are generally found on different plants. The staminate flowers bearing the small yellow anthers naturally give a brighter aspect to the plants which produce them.

*Miquel, "Prol. Fl. Jap.," 1.—Franchet & Savatier, "Enum. Pl. Jap.," I., 22.

The Leather-wood or Moose-wood (*Dirca palustris*) of our northern woods bears the earliest yellow blossoms of any native shrub, unless we include stray flowers of the autumn blooming native Witch Hazel. It is not a showy plant, but on account of the early development (first week of April at the

much earlier, and occasional open blossoms may be found in the first warm days of spring. The cultivated Japanese species (*Andromeda Japonica*) has more handsome and larger flowers, but they are not to be relied on in this latitude. In spite of an unusually mild winter, and among plants in varying situa-

Fig. 38.—*Berberis Sieboldii*—See page 248.

Arboretum) of its modest blossoms it attracts attention, and it deserves a place in every shrubbery. It is a shrub which never requires pruning, as it is of slow, compact growth. There is no very early flowering, broad-leaved evergreen shrub so generally satisfactory as *Andromeda floribunda*. The racemes of white flowers are usually in their best condition about the first week of May, although they are conspicuous

tions, hardly a flower bud survived to open with those of its American congener.

The Leather-leaf (*Cassandra calyculata*) is another early flowering plant of the Heath family which may also be called evergreen. It reaches its fullest bloom at about the same time, but is not so conspicuous as the *Andromeda*, because the flowers, which are somewhat larger, are disposed in a

one-sided raceme and hang downward, so as to be partly hidden by the leaves. Although it is in some respects a more interesting plant than the *Andromeda*, the general effect in cultivation is less pleasing, not only because its flowers are half concealed, but because its foliage is not so bright. Before the best bloom of these plants has passed away another evergreen species, the so-called Water *Andromeda* (*A. polifolia*) opens its blossoms. This little shrub grows a foot or more in height, and in nature is commonly found in swampy situations; but it is easily cultivated in any good, moist garden soil, provided that it does not contain too much lime. The leaves are narrow and dark green above and white beneath. The flowers, which are borne in clusters on the ends of the branches, are nearly globular in shape and have a very small opening at the mouth. The color varies on different plants from white to a decided rose, but generally the color of the flowers is faintly rosy. This charming little plant usually flowers much later in its native haunts, but under the warmer influences of garden cultivation the flowers are developed in early May and last for a considerable time.

Spiraea Thunbergii is fast becoming popular and more widely disseminated. It deserves to be known to every one; for, besides being the earliest of its genus to blossom in the spring, its whole aspect is graceful and the delicate foliage assumes very bright and attractive colors in the late autumn and is persistent after many other shrubs have lost all of their leaves. At Boston it usually begins to flower in the latter part of April, and is whitest with bloom about the end of the first week in May. Three weeks later the seed ripens and falls to the ground, where, under favorable conditions, it at once germinates, and strong little plants may be produced before the end of the season. Many of the flower buds and some terminal shoots were killed during the past exceptional winter, but enough buds remained to develop fully and give the plants a very white and attractive appearance.

Arnold Arboretum.

J. G. Jack.

Notes on Hardy Plants.

ONE of the first native Phloxes to flower is the Ground or Moss Pink (*P. subulata*). Its natural home is on dry, rocky hills and banks, but it can be grown in any light soil. It is common in cultivation and forms dense mats of its creeping stems, so that when established and in flower it displays a solid mass of color. Its flowers are rose-purple, half an inch or more wide; the average height is about four inches. It is surpassed in the size and brilliancy of its flowers by *Phlox reptans*, a species growing much in the same manner, but two or three inches taller, and with reddish purple flowers, often an inch wide. This species is only a few days later than the Moss Pink, and can be grown in shady corners. Its natural home is in damp woods. In a moist, light soil it can be grown in open sunlight. It spreads from creeping stems, and a few plants set thinly soon form a dense bed.

Too much cannot be said in favor of the white California Trillium (*T. sessile*, var. *Californicum*), the beautiful dark green leaves, the large, almost pure white petals, often two inches long by three-fourths of an inch wide. The durability of both flowers and foliage and its perfect hardiness make it second in value to *T. grandiflorum* alone.

The first to bloom of our Dentarias (Tooth-worts or Pepper roots) is *D. laciniata*, a little plant six inches high, bearing a small corymb of pale purple flowers. This species grows in moist, generally in loamy, soil, and in the shade. It lasts but a few days, and its flowers and foliage are quite pretty.

The variety of the Bird-foot Violet (*V. pedata*, var. *bicolor*) is a smaller plant than the typical species, but its flowers are more strongly marked in color and it is one of our prettiest of Violets. It needs shade, or a partly shaded location.

Caltha leptosephala is a species from Oregon and Washington, with white flowers and roundish heart-shaped leaves, much resembling our common Marsh Marigold (*C. palustris*), except in color; but its white flowers are a poor substitute for the bright yellow ones in our species; they are not as large, nor are they produced in such profusion. It would be useful to plant with the common species for variety, and it seems to prefer moist or wet situations. I have not tested its hardiness, but think it is probably hardy enough for New England.

Dicentra formosa, an Oregon species, is now in bloom. Its foliage is quite pretty, and the flowers are half an inch or more long by two-thirds as wide, and of a dull rose-purple color, borne in small clusters on naked stems from the root, eight or ten inches high. It is an attractive plant, but not nearly as valuable in any particular as our eastern *D. exima*. This species is larger, with larger and more numerous flowers of a brighter

rose-purple color. It blooms from early spring until September. Its large clusters of showy flowers are on long naked stems from the root, and both leaves and flowers would be valuable in bouquets. It thrives in the shade, or, if in a light loamy soil, it will do well in open sunlight.

In many localities scattered over our meadows and pastures at this season of the year, wherever it can find a vacant spot in which to take root, may be seen in flower the charming little *Houstonia cærulea*, commonly called Bluets. The centre of the flower is usually yellow, but the outer portion varies from nearly pure white to light blue or pale lilac. It grows as commonly in places as a weed, yet it is never a pest. It is such a low little plant—seldom four inches high—and flowers so early before the grass has attained any size that it seems to be independent and harmless. It is a biennial, but it scatters its seeds, so that when once planted it continues to grow from year to year.

In the autumn of 1887 we received, from a correspondent in St. Petersburg, a few bulbs of *Fritillaria pallidiflora*. They were planted out and have stood two Vermont winters without protection. They have bloomed and borne seed each year. Unlike some other plants of this genus, this *Fritillaria* seems to propagate faster from seed than from scales. Its height is about one foot, and it bears from three to six large bell-shaped, pale yellow or straw colored flowers, an inch and a half long by an inch in diameter. These turn to a dull rose-purple with age. It is an attractive plant, and sure to become popular when more generally known. It thrives in almost any garden soil.

There is more than one form of the *Silene Pennsylvanica* (Wild Pink). We get from Pennsylvania a white-flowered variety which is not showy. But from other localities what seems to be the true type has beautiful pink flowers. It is not so easy to grow as the Fire Pink (*S. Virginica*), but when established will well repay the cultivator, and it comes into flower early. It needs to be set early the previous autumn in order to become established for flowering. Plants set in the spring do not seem to get established so as to flower the same year. It likes a thin shade and a fine loamy soil.

Southwick, Mass.

F. H. Horsford.

Hardy Plants for Cut Flowers.—V.

FEW of the Campanulas are useful for cutting, though all are good border plants, and most kinds are hardy. *Campanula persicifolia* and its many forms, especially the double white, are good for cutting. The double kind grows freely, is easily propagated by division, and the flowers last well when cut. There is a native species, *C. divaricata*, that can be used in the same way as *Gypsophila paniculata*. The small blue flowers of the Campanula have a pretty effect, for they are produced in the greatest profusion on much branched stems, one to two feet high.

Echinacea purpurea is a late summer composite, with large purplish flowers, which are very showy and durable. The plant lasts in bloom fully two months, and we have known flowers to last for weeks in water after having been cut. This plant is often sold as *E. intermedia*, which, with *Rudbeckia purpurea*, are but different names for the same plant. This *Echinacea* is thoroughly hardy, a native of the western states, and easily raised from seed, the seedling plants flowering the first year. Much has been said in favor of *Chrysanthemum maximum* for cutting purposes, and it certainly is a free bloomer, but *C. lacustre* is by far the best plant of the two for this purpose. It flowers at intervals all summer, while *C. maximum* gives but one crop of flowers inferior to those of *C. lacustre*, for these are larger, of good substance, on stems two to three feet long, white, with yellow centre. Both of these *Chrysanthemums* are easily propagated by division and are thoroughly hardy. *C. lacustre* prefers a moist soil.

We had been led to expect much from *Heuchera sanguinea* as a plant for winter blooming under glass. Our plants were strong clumps when lifted in fall, and were kept in a moderately warm house, but they are only just commencing to bloom on being planted in the open air. Judging from other *Heucheras*, it is doubtful if *H. sanguinea* would flower in the open in summer if forced during winter, but this does not detract from its value, as its hardiness is now fairly well proved. The elegant little coral red flowers, borne on long wiry stems, are sure to be appreciated wherever they are given a trial.

While on the subject of red flowers one is reminded that the old scarlet *Lychnis* is a good and useful plant that does not easily lose its hold on the appreciative public. It is a good perennial and very easy to propagate, as it seeds freely. The double variety is the best of the two for those who do not

The Cork Oak in Algeria.—See page 246.

object to a flower because it is double ; but unlike the typé, this may be propagated by cuttings only, and to secure these it is best, after the plant is past its flowering, to cut it down to the ground. Strong base shoots will soon spring up, and these may be readily rooted and will make good flowering plants the next spring. The double-flowered *Lychnis vespertina* is one of the very best double white flowering hardy plants for summer blooming, for it lasts in bloom with us for about three months. The beautiful double rose colored variety of *Lychnis viscaria*,

known as *Splendens*, only needs to be seen to be appreciated. It flowers in abundance, and is a good old-fashioned plant that is too seldom met with. These double *Lychnis* must be propagated by division.

The gorgeous Oriental Poppies last several days if cut just as the buds begin to show their color. They open perfectly in water ; but for those who do not care for their color the soft rose of the variety *Roscum* may perhaps be better appreciated. The plant differs only in the color of its flowers. It

is well known that Poppies die down in summer, and this suggests that some desirable annual be sown near them, such as Mignonette, to occupy the space.

The old-fashioned hardy Pinks are delightful border plants. There are perhaps only two kinds that are really hardy—that is, the pink and white. The florists' named kinds are more beautiful, but are not always able to survive the winters out-of-doors, although easily wintered in a cold frame, and they are well worth this little trouble. The easiest method of increasing the hardy Pinks is by layering in September, and these, when rooted and potted up, make nice stock for planting out in spring.

The Iris family is a numerous one, and to mention all that would be useful for cutting would be a difficult task. *Iris Sibirica hamatophylla* is now covered with dark violet flowers, and is one of the earliest to bloom, and certainly is the best of the Sibirica group. The leaves, while young, are blood-red, but afterward turn green, and the plant often produces flowers three times during the summer and autumn. No garden should be without the true *Iris Florentina*, with its exquisite pale lavender, fragrant flowers. It belongs to and is one of the best of the *Germanica* section, and is the plant from which the Orris-root of commerce is obtained. The varieties of *Iris levigata* are so numerous that one cannot say more with regard to them than that they last well when cut, the unopened buds expand in water, and that the more one grows of the better kinds the more the inclination to try others of the same section.

Passaic, N. J.

E. O. Orpet.

Stove Plants.

AMONG the many old-fashioned stove plants that are worthy of more general cultivation are some of the *Sanchezias*, a very effective group belonging to the *Acanthaceæ*. They are easily managed and of strong and rapid growth, and might be described in a general way as having somewhat the appearance of very strong-growing *Aphelandras*, the latter belonging to the same order. The *Sanchezias* here noted are natives of Ecuador, and should be grown in a warm house, tolerably shaded. They are propagated by means of cuttings, which root readily if given a brisk bottom-heat, and should be potted on from time to time as it becomes necessary, as when starved they are liable to lose their lower leaves. The flowers are tubular in shape, light yellow in color and produced in a terminal panicle. Their effect is heightened by their being partially enveloped by crimson bracts. The species to which special attention is called are, however, grown more for their foliage than for their flowers, though valuable for either. *Sanchezia nobilis variegata* is probably the most widely known species, and has large, opposite, single leaves, variegated with bright yellow, the variegation following the venation of the leaves. *S. glaucophylla* is another excellent species, and is distinct from the first-mentioned in various particulars, one noticeable point being found in the shape of the stem; that of *S. glaucophylla* being round, while the stem of *S. nobilis* is more or less winged. *S. glaucophylla* is also handsomely variegated with yellow, with the addition that the midrib of this species is bright red or crimson. The leaves of these *Sanchezias*, when well grown, attain a length of from twelve to fifteen inches and a breadth of four to five inches, and they possess much decorative value; but it should be remembered that to grow them well they need to be kept clean, both mealy-bug and aphid being very partial to them.

Duranta Baumgartii variegata is a pretty little shrub of South American origin, and though frequently found in a warm house, need not necessarily be grown in a high temperature, as it may be used for out-door work in summer. It has opposite leaves of fair size and marked with bright yellow. This *Duranta* is easily grown in light loam, but should not be allowed to become very dry or it will be attacked by red spider. Cuttings of soft wood root readily, and the young plants should be pinched back occasionally to keep them in shape, as the natural habit of the plant is somewhat straggling.

Mussaenda frondosa is a charming stove flowering plant from Ceylon, and, though in cultivation for many years, it is very seldom seen. It belongs to the *Rubiaceæ*, and would prove a valuable addition to many collections on account of the striking combination of colors in its flowers. The flowers are produced in racemes, and bear some resemblance to a yellow Jasmine; but they are surrounded with pure white bracts, the latter being formed by the enlargement of one segment or division of the calyx. *M. frondosa* is also increased by cuttings, which may be put in at almost any time, providing the shoots thus used be moderately soft, though as

this plant usually flowers in the late summer or in autumn, it is well to root the cuttings early in the spring, so that the plants may be grown on rapidly for fall use in the conservatory. The *Mussaendas* should be potted in a light mixture, equal portions of loam and peat, or leaf-mould, with some sand, making a satisfactory compost. The pots should be well drained, as the plants enjoy liberal watering during the growing season, and a moist atmosphere with some shade will be found beneficial. There are other species of *Mussaenda* besides the one referred to, some of which are but little known except to botanists.

Holmesburg, Pa.

W. H. Taplin.

Orchid Notes.

DENDROBIUM SUPERBUM.—This is a very handsome species of a pendulous habit, almost always becoming deciduous just as the flower-buds begin to grow; it has ovate-oblong obtuse leaves, which give the stems a very pretty effect after the growth is finished. The stems grow from two to three feet long, and from each side of these the flowers proceed in rows, each measuring three to four inches in diameter. They are of a beautiful rose-purple color, with a fringed, rich purple lip, marked with a pair of sanguineous spots at the base. They last in perfection three weeks, if kept in a cool, dry atmosphere. The flowers have a peculiar Rhubarb-like odor, particularly sweet early in the morning, when the sun shines on the house and before the ventilators have been opened. The plants here are in baskets suspended from the roof, in a light, airy place in the summer-flowering Cattleya-house. They enjoy a compost of fibre and sphagnum moss, with a little charcoal to keep it sweet. The plant likes a good supply of water when growing. It is most generally known under the name of *D. macrophyllum*, the name formerly applied to *D. Veitchianum*.

DENDROBIUM FARMERI.—This is an evergreen, compact-growing species, with delicately beautiful blooms and a habit similar to that of *D. densiflorum*. The stems are clavate, from a small knob-like base, and are deeply furrowed, so as to become quadrangular. At the point of the stems are three or four ovate, leathery leaves, and from them grow the beautiful, loose-drooping racemes of numerous flowers, which have ovate-obtuse sepals, the larger petals being yellowish white flushed with pink. The lip is straw colored, with a rich yellow centre, and is denticulate at the margin. It expands its flowers in April, and lasts several weeks in beauty when kept in a cool, dry place. We grow this species in baskets suspended from the roof, in the same way that we treat *D. superbum*. It likes a fair quantity of moisture when growing, otherwise it will become covered with thrips; it should be kept comparatively dry when at rest, or it will not bloom freely. We grow this in sphagnum moss, which appears to suit it admirably.

Staatsburg-on-the-Hudson.

F. Atkins.

CYPRIPEDIUM ROTHSCILDIANUM.—A plant of this beautiful *Cypripedium* is now in flower in the collection of Orchids owned by Hicks Arnold, Esq., in New York City. It is entirely distinct and a noteworthy acquisition. It is a vigorous plant, having stout, very broad leaves, from the base of which is produced a scape bearing several flowers. The dorsal sepal on first opening was white, heavily marked with broad lines of a dark purple; after five or six days the ground color turned to a light yellow. The petals, which measure from four and a half to five inches in length, stand boldly outward, and are striped and spotted with dark purple, the edges being furnished with numerous hairs. The staminode is a distinctive feature in this variety, being covered with bluish hairs. The lip is very similar to that of *C. Stonei* in shape; the color, however, is somewhat darker. The plant requires a temperature slightly warmer than the majority of *Cypripediums*, and dislikes being in a large pot. Peat, moss and turfy loam, in equal proportions, make a good compost. With a temperature of sixty-five to seventy degrees it will be found an easy plant to cultivate.

Summit, N. J.

A. Dimmock.

Fritillaria armæna.—This is a small sized species, about four inches high, from Asia Minor. The stems are clothed with pale green lanceolate leaves, and the dark purple, bell-shaped flowers, borne on pedicels an inch and a half long, appear singly or in pairs at the top. The pedicels turn downward at their extremities and thus the flowers assume the nodding position characteristic of the genus. At the Bussey Institute (a department of Harvard University), I noticed, during the latter part of April, a group of a yellow-flowered variety of *F.*

armena in an exposed border and it is quite as attractive as the type. The flowers of the species and its variety are almost three-quarters of an inch long and the same in width at the mouth. Both succeed satisfactorily when planted in the fall and given the same treatment under which Hyacinths and Tulips thrive. They are well worth a place among the sturdy little flowers of early spring.

Harvard Botanic Garden, Cambridge, Mass.

M. Barker.

Transplanting.—Nearly every vegetable will endure transplanting without permanent injury, and this practice simplifies garden work and adds much to the area of a small garden. Lettuce can grow a month or more in the seed-bed before the transfer; Beets sown in the same way can be set out in the garden when the ground is warm, and will be two or three weeks in advance of those planted from seed in the spring, and the roots, if pains is taken in the work, will be of good form; Peas can be transplanted into moist or well watered soil and will grow thriftily; Beans do best if grown in pots or flats, as many seeds in a place as would be planted in a garden, and, when well up, shifted dirt and all into the out-door hills about the 1st of June. By this method we get Cucumbers much earlier, and they can be grown to the third leaf before they are set. All forms of Cabbage, Onions and Celery should be transplanted; and melons in this way can be had much earlier. Parsnip, Carrot, Salsify and roots of that nature are not improved by transplanting.

Plants of any kind should be given a permanent home before they are overgrown in the seed-bed. Too large plants are less likely to make perfect vegetables than those set when at the proper size. Seedlings will only attain a certain point of growth in flats, and when this period of stagnation is reached no more growth can be expected without a change of soil or location. If the plants have good roots and are set toward evening in freshly prepared soil they will live. A strong wind is more destructive to young plants than the sun's rays, and if the soil is well prepared and pressed lightly about the roots, most plants will grow even in the sun without shelter. A bath in thin mud is a good preparation for the roots of some plants when they must be set in a dry time. Watering after or during the time of transplanting is much practiced, but, unless the weather is very dry, the plant will do as well without if properly set. Cabbages and like plants, if lifted a day before they are to be set and left in a cellar, will make a new growth of root, so as to gain rather than lose time by the day's delay.

West Springfield, Mass.

W. H. Bull.

Little Known Vegetables.—As stated by a correspondent on p. 228 of GARDEN AND FOREST, several European vegetables deserve to be better known in this country. We have few vegetables of better quality or of easier culture than Celeriac. It possesses plainly enough the delicious celery flavor and yet is sufficiently different from it to be a distinct vegetable. By packing in earth or sand the roots may be preserved in a cool cellar until spring without losing their fine quality.

I have always started the plants of Celeriac in the hot-bed or cold-frame, but I now think that if sown very early in spring on a nicely prepared bed in the open ground the seed would germinate sufficiently well to produce a good crop. The plants are hardy like those of Celery and endure frost well. They should be given rich ground and be well cultivated, but hilling up is not as essential as it is with Celery.

Another vegetable that should be more common in our gardens is the tuberous-rooted or Hamburg Parsley. This is truly a Parsley with a root the size of a small Parsnip and with a flavor peculiar to itself. The plants should be started in the hot-bed or cold-frame, as the seeds, like those of the common Parsley, are rather slow to germinate. When of sufficient size the plants may be set in a well prepared bed in the garden, in rows two feet apart. The roots are rather slow of growth, becoming fit for use in September or October. Like the Celeriac, they may be preserved through the winter in the cellar by packing in earth or sand.

To my own taste, both the Celeriac and the Hamburg Parsley are equal to Salsify as contributions to the table. To some, however, their peculiar flavors are less agreeable. I have observed that in many persons a taste for the characteristic flavors of vegetables belonging to the *Umbelliferae* needs to be acquired.

University of Wisconsin.

E. S. Goff.

Under the Roses.—Beds of hardy Roses are not attractive, either in the early spring, when the leaves are forming, or after the flowering period in June or July. I have found it very advantageous to plant between the bushes the yellow and blue varieties of *Viola cornuta*. A large Rose-bed in my gar-

den, thickly planted with *Viola cornuta*, var. *lutea*, is now a blaze of brilliant color. The plants reproduce themselves with great facility from seed, and in a few years numbers can be obtained. They also increase by spreading, and soon yield very large clumps. The seedlings vary somewhat in color and form as well as in foliage, but are almost always handsome, and frequently as large as an average Pansy and hardly less beautiful. They are also faintly, but distinctly, fragrant. They continue in bloom until late in the fall, but the flowers in summer are somewhat smaller, as a rule. Planted near Pansies the two forms hybridize easily, but I have not obtained any noteworthy flowers in this way. Two very fine new forms of *V. cornuta* are sold under the names of Admiration and Magnifica. These, perhaps, belong to the class of Tufted Pansies, and are respectively violet-blue and purple-violet. They appear to be not less hardy than the species, standing the winter in the open ground without other protection than the manure thrown upon the Rose-bed in the fall. The plants do very well even in a light loam, but require plenty of water in the summer.

Newport, R. I.

W. G.

Iris Gatesii.—Joining Mr. Orpet in his praise of *Iris Susiana*, I hope he will allow me to state that now we have a plant which excels it in beauty. *I. Gatesii* was discovered by Mr. Sintenis in the mountains of southern Kurdistan, and was introduced by me to Europe two years ago. The flowers on stalks as thick as a man's finger and twenty-five inches high, show well above the foliage. They are in some cases double the size of those of *I. Susiana*, and the coloration is not so sombre, but far more delicate and more beautiful. The ground color is creamy white, the very massive standards, as well as the falls and claws, are dotted over with very minute silvery gray points and also adorned with a most delicate network of silvery gray lines. The beard is ochraceous yellow, and, seen from a distance, the flower looks yellowish gray. This Iris has the largest flower of any of the genus so far known, and, apart from its size, the flower is striking and of a highly aristocratic appearance. There are, moreover, some other novelties coming on, one of which resembles *I. Susiana*, but with markings of a crimson color.

Forestry in North America.—III.

Part II. sets forth the fundamental principles of silviculture. The author maintains, with justice, that the principles of silviculture hold good all over the world, but adds that the illustration of these principles must be taken from a limited area. For this purpose he has chosen the timber-trees of western Europe on the fiftieth degree of north latitude and the countries immediately to the north and south of it—in other words, the forest-trees of England, northern France and the greater part of Germany. These species the author does not attempt to describe; he assumes that his readers are familiar with them. The first chapter dwells upon the external conditions which influence the development of forests. He says:

"Soil, including subsoil, and atmosphere are the media which act upon forest-vegetation, and they together are in silviculture called the 'locality.' The active agencies, or factors, of the locality depend on the nature of the soil and the climate, the latter being governed by the situation. The sum total of these factors represents the quality or yield-capacity of the locality. The forester requires to be well acquainted with the manner in which soil and climate act on forest-vegetation, in order to decide in each case which species and method of treatment are best adapted, under a given set of conditions, to yield the most favorable results."

Every forester knows that, on good soil and under conditions otherwise favorable, a timber-crop is heavier than one of equal age grown under less favorable conditions. In the concluding section of this chapter the author shows how we may use this fact in order to assess the quality of a locality. Numerous measurements of woods of different species and ages, grown under different conditions, have been made in Germany on a systematic plan, and from the data thus obtained yield-tables have been calculated, showing the volume of timber produced at different ages on a given area by the principal species on localities of different quality classes. Using the yield-tables published for the Scotch Pine by Wilhelm Weise, now Professor at the Forest School of Karlsruhe, the author shows that at the ages of 50 and 100 years the volume per acre of timber only, not including faggots, in localities

which, according to their yield-capacity, are classed as first, second and third class, is as follows :

	I.	II.	III.
Cubic feet at the age of 50 years, . . .	5060	3940	2700
Cubic feet at the age of 100 years, . . .	8390	6410	4910

The figures of these yield-tables Dr. Schlich has found, to a certain extent, to be applicable to Scotch Pine-forests in England. Some of the data of those tables have already been used in the preceding remarks. They can also be used in order to assess the yield-capacity of any locality stocked with Scotch Pine in England. Eventually, similar yield-tables must be prepared for the principal forest-trees of North America, and this is a work which ought to be undertaken by the Federal Government, or by the governments of individual states, for the benefit of forest-proprietors.

Before, however, such work can be undertaken with any prospect of useful result, two conditions must be fulfilled: The first condition is, that a unit of measurement must be adopted for all classes of timber. In countries with the metrical system it is the cubic metre; in Great Britain, India and the Colonies it is the cubic foot—and this it may, perhaps, be found convenient generally to adopt in North America. The second condition is, that state forests are constituted, permanently demarcated so as to be safe against encroachment, and that their management is properly organized. Without such public forests it will not be possible to prepare yield-tables or to collect any other statistical data necessary to serve as a guide to forest-proprietors in the proper management of their estates.

The second chapter deals with the shape and development of forest-trees, but we can refer only to what the author says regarding height-growth. Building again chiefly upon researches made in Germany, Dr. Schlich explains how the different species have a different mode of height-growth. On page 163 an instructive diagram will be found exhibiting the relative height-growth of Spruce, Silver Fir, Beech and Scotch Pine in a locality of the first quality. At the age of fifty years the mean height attained by each species is as follows :

Scotch Pine,	64 feet.
Beech,	60 "
Spruce,	55 "
Silver Fir,	40 "

At a later age Spruce and Silver Fir take the lead, while Beech and Scotch Pine remain behind in the race; and when 120 years old the order of the species stands as follows :

Spruce,	118 feet.
Silver Fir,	108 "
Beech,	102 "
Scotch Pine,	97 "

Scotch Pine and Beech, therefore, make the principal height-growth during the first period of their life, whereas Spruce and Silver Fir continue to grow vigorously in height to a much greater age, Spruce more so than Silver Fir. The progress of height-growth of the different species is much affected by the character of the soil, by elevation, the more or less crowded state of the wood and other circumstances, but under otherwise similar conditions it will always be found that deep, fresh, fertile soil produces much taller trees than shallow, dry or rocky soil.

In the third chapter, which deals with the character and composition of woods, the author points out that the object of silviculture is not to rear isolated trees, but considerable masses of trees, forming more or less crowded woods. Pure woods consist of one species only, or of one species with a slight admixture of others, whereas mixed woods contain a mixture of two or more species. The advantages of mixed woods are clearly set forth, and the author's remarks on this subject may be specially recommended to the attention of proprietors and managers of woodlands in America.

The last and most important chapter deals with the silvicultural systems—that is, the different methods under which the creation, regeneration, tending and utilization of woods are effected. The three well known classes are: first, high forest, originating in seedlings, either self-sown or artificially raised; second, coppice, which regenerates itself from coppice-shoots; and third, coppice with standards, a combination of seedling and coppice-forest. The modifications of these three main systems are numerous, and particularly the treatment of high forest has developed in a great variety of ways. On this subject we must refer the reader to the manual. These are matters which can hardly be fully understood without opportunities for obtaining practical experience of forests treated under the various systems described. Such opportunities cannot at present be found in the United States. For

that purpose students will have to go to Germany or France. And this necessity of studying forestry abroad will continue until a commencement on an adequate scale has been made in the United States to manage forests on a comprehensive and well considered plan.

This remark must not be understood to mean that those who have not studied forestry in Germany or France are not competent to undertake the management of forests in America. A commencement must be made; the sooner it is made the better, and it would be a mistake to wait until a sufficient number of men, trained in their profession abroad, were available. Any one, however, who can afford the time for studying forestry in France or Germany will find such study the most useful preparation for forest-work in America. The different systems of treatment which have been developed in Germany for the Scotch Pine, the Spruce, the Silver Fir, the Oak, the Ash and the Beech cannot, as they stand, be applied to the forest-trees of America and to the widely different conditions of climate which are found in the different regions of the United States. New methods must be devised on the ground of actual experience in America, but a thorough practical knowledge of the European system will be found most useful as a guide. The operations that will most completely secure the regeneration of the White Pine, the Douglas Fir, the Redwood, the Long-leaved Pine and other forest-trees of North America, either naturally or by sowing and planting, will doubtless be similar to those which have been brought to the present state of perfection by the persistent labors of foresters in France and Germany, particularly in Germany. The same remark applies to all other operations necessary to organize the systematic management of forests in America, the demarcation of forests, the settlement of forest-rights, the division of the forest into blocks and compartments,—the preparation of working-plans, the arrangements for its protection and the organization of the staff of administration, the executive and protective officers. For the arrangement of all these matters in America the experience which has been gained in Europe will serve as a most useful guide, and it would be a waste of time, of strength and of money not to utilize that experience to the utmost. Hence it will be of great advantage in America, as it has been under analogous circumstances in India, if as many as possible of the foresters who are to inaugurate the new system of forest-management have received a thorough training in their profession, both practical and theoretical. Nor is there any doubt that under existing circumstances the forests of Germany or France, and particularly those of Germany, offer the best opportunities for such professional training.

Allusion has already been made to the necessity of commencing the collection of statistical data upon which to build yield-tables for the more important of the American timber-trees. This is only one of numerous important subjects which must be studied systematically by means of scientifically arranged researches, the object of which will be to ascertain mode and rate of growth, to determine the effect of different methods of treatment and to obtain replies to many questions connected with forest-management. It has already been said that the duty of conducting these scientific researches, which are necessary to aid systematic forest-management, must be undertaken by the state, because it is not likely that private forest-proprietors will devote their time and their means to such matters. Those who may undertake these researches should certainly have received a complete professional training in forestry and in the sciences upon which the forester's profession is built up. They ought to have seen themselves how such researches are conducted in those countries where forestry is best understood. A commencement of collecting statistical data concerning the forests of North America has already been made by the Forest Division of the Department of Agriculture; it is therefore reasonable to suppose that the state will undertake this part of the work. It cannot, however, be carried on with any prospect of satisfactory results unless state-forests in the different great forest-regions are formed and managed on a good system.

It might be deemed preferable not to attempt the systematic management of forests on a large scale until their scientific researches have given results which admit of practical application, and until they have furnished definite precepts for the treatment of the different classes of forests. Such a proposal should not be listened to for a moment. A commencement must be made at once; the sooner the better. The best must be done under the circumstances. There may be failures, and the best method of treatment will certainly not be hit upon at once. The shrewd common sense, the keen eye to business of Americans, aided by a good knowledge of forest-management as practiced in Europe, will eventually hit upon the

right method in each case. The art of treating the American forests to the best advantage must grow up as the result of practical work on a large scale. The development of systematic forestry in America, however, will be greatly aided by the experience gained in other countries, and Dr. Schlich's Manual will doubtless give a powerful impetus to systematic forest-management in the United States.

Bonn, Germany.

D. Brandis.

Correspondence.

Grapes for Home Use.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. Powell's criticism of my list of Grapes for family use in GARDEN AND FOREST for April 30th, coming from an experience in a different latitude and soil, is valuable. This fact should be borne in mind by the reader, and it should be remembered, too, that the original information was given to a novice living in my latitude and having a soil differing from my own only in being more sandy. I concur in Mr. Powell's estimate of the quality of the Worden. I have been insisting on its superiority to the Concord in this respect for the last ten years, and yet we often hear it asserted that the Concord is the best Grape grown, and that Worden is only another name for it. I wish I could endorse the claim of Mr. Powell that the Worden keeps better and does not break (crack) so easily as the Concord. These have been its chief faults with me; but, after all, I am not certain that its resistive force in this respect is feeble than that of the Concord under the same conditions. A cross of Worden and Herbert would be desirable if it resulted in a "swapping of jackets."

I did not mention the Massasoit for the simple reason that it is a poor setter. El Dorado has the same defect. I have never yet been able to get a perfect cluster from either of them. Now, I should be grateful to Mr. Powell if he will teach me how to secure perfect clusters on these two varieties. Other growers accomplish this, and what is lacking in my soil or treatment I never could discover. The Lindley is also subject to the same defect with me, and so are many others of Rogers' hybrids. Herbert leads them all, as far as I have tested them, in size of berry; but Wilder exceeds it in size of clusters, which often weigh a pound and more, while half that weight would be heavy for a cluster of Herberts.

The quality of the Duchess is beyond question, but it is the first to show symptoms of black rot, and bagging the clusters before blooming has not entirely excluded the fungus. It is strictly a variety for amateurs in this locality, and requires much coddling for success.

I am glad to hear good words for Diamond and Hayes from disinterested sources, but these are comparatively new, and have not yet, with me, reached the five-year probation fixed by Downing as necessary for determining the proper position of a new Grape.

The time has passed when it was only necessary to plant the vines and allow them to take care of themselves. Success with this fruit, as well as others, in these days of insects and fungi, is only gained by constant and intelligent care. The hardest disease-resisting kinds are the only ones fit for indifferent and careless cultivators to plant. They can, if they will, learn valuable lessons from these, and be better able to care for the better and more civilized kinds.

Montclair, N. J.

E. Williams.

Durability of Fence-Posts.

To the Editor of GARDEN AND FOREST:

Sir.—I am told, though not authoritatively, that a fence-post will last much longer if put in the ground upside down. Can you let me have either a confirmation or refutation of this?

Mount Airy, Philadelphia.

B.

[Some years ago Dr. W. J. Beal, of the Michigan Agricultural College, selected sticks of thirteen different kinds of timber. Each stick was cut in two in the middle, and each of these was split, making four sticks from each one. One set was placed in sandy land, and the other in clay land; in each place putting near each other a stick "top end up," and its mate "bottom end up." In some cases those with top down lasted best; in some the reverse was true, while in others there was no perceptible difference. The conclusion reached was that, so far as durability goes, it made no difference which end of the post was set in the ground.—Ed.]

Plant Problems.

To the Editor of GARDEN AND FOREST:

Sir.—Two or three years ago a certain neglected meadow in this neighborhood was entirely covered with *Blephilia ciliata*, only a plant here and there of any other species being discernible, presenting in full bloom, as may be imagined, a scene of rare beauty—a vivid reflection of the sky's own blue. Next year the prevailing plants were *Lobelia spicata* (largely predominating), *Achillea Millefolium* and *Rudbeckia hirta*, conspicuously interspersed with *Lilium Canadense* and *L. superbum*, and only an occasional plant of *Blephilia* among them all. The last season, the third in order, I counted over a dozen conspicuous flowering plants all blooming at one time in charming prodigality and confusion—a veritable flower-garden of eight or ten acres in extent, and of Nature's own ordering—and the *Blephilia* still more rare, having practically disappeared. The plant in question being a perennial, what became of it the two previous years, and why, at least, could it not hold its own with some of the plants referred to?

In the late summer of last year the beautiful American Centaury (*Sabbatia angularis*) was here one of the most common of plants—freely distributed over neglected fields and waste places. For the five years previous, or since the season of 1884, when it was equally abundant, scarcely a plant was to be seen. During my ten years' residence here these are the only instances where I have known it to bloom thus generally. Why has a biennial plant grown and flowered at such rare intervals, and simultaneously over an extended area?

Fairview, W. Va.

W. E. Hill.

Recent Plant Portraits.

Botanical Magazine, May:

EREMURUS AURANTIACUS, t. 7113; a noble Asphodel from the Caucasus, and, like its congeners, a most desirable hardy rock-plant, although rather difficult to manage and requiring careful drainage to prevent the thick root-stalks from rotting during winter.

ABIES BRACHYPHYLLA, t. 7114; a beautiful hardy Japanese Fir, with broad, dark green, distichous leaves, quite white on the lower surface from the broad bands of stomata, and one of the group of Japanese trees of which *A. firma* should perhaps be considered the type. As the editor, Sir Joseph Hooker, points out, "no one but a botanist traversing the islands of Japan, with an eye especially directed to its Silver Firs, can determine whether species or varieties or synonyms are represented under the above names" (*A. brachyphylla*, *A. homolepsis*, *A. Veitchii*, *A. firma*, etc.)

PASSIFLORA MIERSII, t. 7115; a graceful Passion-flower from Brazil, belonging to the section Grenadilla; a slender glabrous climber, with rather small flowers with white petals and purple corona.

BERBERIS VIRESCENS, t. 7116; under this name Sir Joseph Hooker proposes a new species for a Himalaya Barberry, first detected by him in Sikkim in 1849, and recently introduced into cultivation. The flowers are small, a third of an inch in diameter, in fascicles or short racemes, and are sulphurous or greenish yellow. The fruit is oblong or narrowed upward, compressed, scarlet or black, and one-seeded. As this Barberry grows naturally at an elevation of 9,000 feet or more above the sea, it may be expected to survive the winters in our Northern States.

PRIMULINA SINENSIS, t. 7117; a very remarkable Gesneriaceous plant, with the habit and foliage of a Primula, a native of southern China. The lobes of the spreading corolla are white, with broad violet-purple borders. This botanical curiosity was introduced into England from the Hong-Kong Botanical Garden in 1887, and flowered last summer at Kew for the first time.

Notes.

The sixteenth edition of Dr. A. Garcke's "Flora of Germany" has just been published by Parey in Berlin.

The Garden reports that *Shortia galacifolia* has flowered at Kew, and "judging from its health and vigor, is likely to become popular" in England.

The corner-stone of the Washington Memorial Arch in this city will be laid on Decoration Day with appropriate services of a religious and military character.

The Garden (London) speaks of a seedling Tuberous Begonia, at the nurseries of the Messrs. Laing & Sons, in which the semi-double blooms of large size and rich self crimson have

florets whose edges are handsomely fimbriated. This is a new break in these plants, and such a margin will help to relieve the flower of any formality.

A German journal names *Gladiolus* Snow White as decidedly the best white variety of the flower and recommends it to the attention of its readers as an important American novelty.

The description of the Celtis or Nettle-tree, published some months ago in GARDEN AND FOREST, has attracted much attention in Europe, and a long abstract of it was recently published in *Gartenflora*.

It is said that this summer will be an exceptionally good time to visit the Yosemite Valley, as the snow-falls of the past winter were the heaviest on record and the volume of water in the falls will therefore be unusually great.

The proposed alteration of the tariff, by which a duty of twenty per cent. will be imposed on plants, was discussed at a recent meeting of the Philadelphia Florists' Club and a resolution protesting against the proposed duty was passed. It is claimed, however, that this resolution does not represent the true condition of opinion among the members of the craft in Philadelphia, as the resolution was passed by a bare majority in a vote comprising about one-fifth of the membership of the Club, and the question will probably be called up at another meeting.

The *Illustrierte Gartenzeitung*, of Vienna, says that *Primula obconica* was brought to notice in Germany by descriptions and an illustration, which, in 1886, it reproduced from an American journal. At a horticultural congress held two years later it was agreed that the plant "did not fulfill the expectations that it had excited," but, the writer continues, later experience has been different, as admirable plants of *P. obconica* were shown during the winter just past by all the florists of Vienna. Now he doubts, however, whether it will preserve its popularity, owing to the alleged poisonous character with which it is credited by American florists.

One of the large specimens of *Livistonia Sinensis* in Horticultural Hall, Fairmount Park, Philadelphia, has recently perfected its first crop of seeds. The plant is about twenty-five feet in height and it bore three large spikes of flowers which were followed by a liberal quantity of seeds, the latter setting in the spring of 1889 and ripening in April of the present season. As an instance of the readiness with which this species germinates, it may be added that some of the seeds that fell from the plant before the crop was gathered were found to have germinated while lying on the ground beneath, which was carpeted with *Selaginella*.

German horticulturists complain rather bitterly that it is difficult for them to compete with the firms which import flowers during the winter from southern Europe, and especially from the districts about Nice. They envy in this respect their brethren in our northern towns, where as yet all the flowers used in winter are grown under glass near home. They say that to grow Roses, for instance, as American florists grow them, in immense quantities for the mid-winter trade, would be a ruinous undertaking, their only profit coming from late blooming sorts which are in request after the end of February, when the southern supply falls off.

Columbines are now in the first flush of their bloom and beauty. Among the forms in flower are *Aquilegia Olympica*, *A. glandulosa jucunda*, *A. Canadensis*, *A. alba grandiflora* and *A. Sibirica*, with hybrids in great variety, double and single, long-spurred, short-spurred and no-spurred. The Columbines, ranging through reds, blues and yellows, seem to disprove the oft-quoted theory that these three colors are never found in the same genus of plants. Other hardy flowers which have bloomed during the week are *Scilla campanulata*, German Iris, *Anemone sylvestris*, the hybrid Violets known as "Tufted Pansies," and *Daphne Cneorum*.

California correspondents speak of the great success which has attended the "colony system" recently introduced in the southern part of the state. Tracts of land are laid out in small holdings and apportioned among a body of immigrants, who, upon their arrival, find everything ready for work. A body of colonists from Holland who arrived not long ago at Merced, found houses built and gardens and orchards arranged, more than two thousand acres having been planted with fruit-trees and vines; and fifteen English families were established a few weeks ago at Bakersfield, in Kern County, each receiving a forty-acre holding similarly prepared.

A considerable quantity of fine vegetables come to this city from Europe during the winter, such as Brussels Sprouts, with

Endive and other salad plants. Romaine Lettuce is now coming in from Long Island, but an occasional lot still comes from France. The imported Lettuce is very large and fine flavored and sells for \$2.50 per dozen. A few Globe Artichokes still arrive and sell for \$20 per hundred. The very finest heads are said to be raised in Algeria, whence they are shipped to France and are brought here in boxes of ice which are furnished by the importers. Last week a few of the melon-shaped fruits of the Pawpaw-tree (*Carica Papaya*) came into market from the West Indies and a few Cantaloupes from Cuba.

Mr. T. Laxton, well known as the originator of so many varieties of the best Peas, says that if all the advances in earliness claimed for new varieties within the past twenty-five years were added together, Peas could now be had before New Year's. And yet the claims of originators have not been very wide of the truth. For some reason, very early Peas tend to come later year after year. This may be because the earliest peas to ripen are lost before the crop is gathered for seed, and this constant rejection of the earliest seed tends to fix the habit of later ripening. It happens, too, that very often the earliest peas to ripen are used for the table and this helps on the selection for seed of the peas which ripen latest. This constant loss necessitates the production of new varieties by the careful selector or hybridizer. A similar process goes on in regard to the height of Peas, as the dwarfier plants get lost or left in harvesting and the tendency to revert to old forms asserts itself. In this way the so-called dwarf varieties come at last to be tall. Again, quality may deteriorate by cross-fertilization, so that these persistent tendencies can only be counteracted by constant watchfulness and the production of new forms.

Michigan is one of the states in which a bounty is paid for the extermination of the English sparrow. But according to a late bulletin from the Experiment Station of that state the bounty too often helps forward the destructive work of the sparrows by killing other insectivorous birds. Too many of the county clerks cannot distinguish the head of an English sparrow from that of a linnet or a thrush, and money is actually paid for the destruction of such valuable birds as the song sparrow, the red-polled linnet and the evening grosbeak—birds which are protected by the state, under a law which makes their slaughter a misdemeanor to which a penalty of five dollars is attached. The bulletin gives such illustrations and descriptions as will enable the officers to distinguish between the native birds and the foreign nuisances. Nevertheless the law should be amended so as to make it the duty of county clerks to inform themselves and to collect a fine for every native bird offered for a bounty. It is to be remembered that the English sparrows destroy fruit, grain and vegetables. They attack blossoms, young fruit and grain at harvest-time. They eat some insects, but they protect more than they feed upon by driving away native insectivorous birds. Wrens, martins, swallows, blue-birds and even robins and wild pigeons suffer from these marauders, who destroy nests, young birds and eggs for no other apparent purpose than to drive these birds out of the neighborhood.

It is interesting to find in the shrubberies near Mount Morris, in Central Park, a number of large well established plants of the old white Indian Azalea, *Phœnicia*, unharmed by the winter, and in full flower. The excellent condition of these plants testifies to the fact that the Indian Azalea, or some of its varieties, at least, can be grown in much more severe climates than these plants have been supposed capable of flowering in. Only a faint idea of the beauty of the Indian Azalea in flower is obtained by seeing it grown as a pot plant, as the flowers quite hide the foliage, and the real charm of their delicate colors can only be appreciated when the plants are brought into immediate contact with the bright green of the vernal turf or the dark green of some broad-leaved evergreen plant. Several varieties of these Azaleas could be grown, no doubt, in this climate if a little care was taken in selecting sheltered positions for them and in furnishing a slight winter protection; and the experiment is certainly worth making. Azaleas in cultivation are all derived from plants cultivated originally by the Chinese in the southern part of the empire, or from the gardens of central and southern Japan. The so-called Indian Azalea, or some of its forms, grows far north in Japan in a climate as severe as that of New England. It is improbable that these northern forms have ever been introduced into our gardens, where they are possibly destined to give birth to a new race of garden Azaleas, which, there is every reason to believe, will prove as hardy and satisfactory here as have many other plants from the same region.

The Preservation of Natural Scenery.

THAT pleasing natural scenery has a positive value of its own is a proposition which will hardly be disputed, and yet few persons seem to realize that, if this is true, the destruction of such scenery must be a loss to the common wealth. Occasionally a community comes to understand that a placid, forest-bordered lake or a mountain stream tumbling through a gorge is not only a delightful possession, but gives an additional pecuniary value to all surrounding property. Now and again we hear of a rural community which, without any sordid motive, forms a generous trust to purchase some charming natural object to protect it from being vulgarized or destroyed, and to hold it free for public enjoyment forever. The preservation of Chittenango Falls (see vol. ii., page 373) affords a conspicuous example of this enlightened public spirit which cherishes natural beauty as an inheritance which should, if possible, be handed down without impairment to posterity. As a rule, however, no organized effort is put forth to protect these picturesque places from invasion, and one by one, especially in the more thickly settled parts of the country, the axe and fire, or the equally destructive holiday picnic, is robbing them of every element which makes them poetic or refreshing to the spirit.

A few weeks ago Mr. Charles Eliot invited attention in these columns to several fragments of the primitive New England wilderness which still survive within ten miles of the Boston State House. One of these is the steep moraine, upon which are grouped the great Waverly Oaks (page 85); another is the remnant of a Pine-wood; a third is a dark stream, over which, from rugged banks, hangs a forest of Hemlocks, and there are other bits of scenery equally characteristic and attractive. But even if there was a manifest desire to save these and other examples of unsophisticated nature, it would be difficult to do so under existing laws. The Chittenango Reservation was authorized by special act of the Legislature, although in this

state a general law has been enacted to provide for a body corporate with the power of succession, and authority to acquire lands and hold them forever for public use. A movement is now on foot in Massachusetts to "facilitate the preservation and dedication to public enjoyment of such scenes and sites as possess uncommon beauty or historical interest," under the auspices of the Appalachian Mountain Club. The scheme looks to the establishment of a Board of Trustees empowered to acquire parcels of real estate, and to hold them, free of taxes, open to the public. It was in the interest of this movement that a noteworthy meeting was held in Boston on Saturday last, at which a committee was appointed to perfect a plan under which it is hoped that private generosity will be able to rescue from danger many scenes of natural beauty and hold them for the enjoyment of coming generations.

The Yosemite Valley, the Yellowstone Park, the Niagara Reservation are examples of what government may attempt in this direction; but still more effectual than government aid would be an enlarged appreciation by the great body of the people of the soothing and uplifting value of beauty and grandeur in natural scenery. Such an appreciation would manifest itself not only in securing land for city parks or in saving to some town its deep glen, cool with falling water, tree-shaded and fern-embroidered. It would ensure for the parks proper planning and maintenance, and for the glen not only the mere preservation of its native graces, but the addition of a new charm to every feature by skillful and reverent treatment. It would be felt not only in a few isolated acres specially guarded by law, but over the whole face of the country. It would protect many a mountain slope from being scarred by railroads, when they could have been constructed as well without defacement of the scenery. It would be seen in the preservation of every pleasing prospect and in the treatment of every country roadside. But until there is a public conscience to protest against the obliteration of natural beauty wherever found, these efforts to save a little here and there deserve the active and hearty co-operation of all forward-looking and public spirited citizens.

IN a recent communication on the proposed changes in our tariff on lumber made to the *Canadian Journal of Commerce*, Mr. William Little, of Montreal, one of the best informed lumber-men of America, discusses the present condition of the standing pine in the states of Michigan, Wisconsin and Minnesota, once the chief source of the pine supply of the United States, and reaches the conclusion that the great White Pine-forests of this country have vanished practically for all commercial purposes. He takes, as an illustration of his position, the Pine-forests of the lower peninsula of Michigan, in which it was estimated by the officers of the United States Census that there were standing in 1880 29,000,000,000 feet of merchantable White Pine. In 1889 the editor of the *Chicago Timberman* made an investigation of the merchantable pine standing in the same region and found only 3,000,000,000 feet. Some of this was cut last winter, so that, if these figures are correct, there is not now pine enough in the lower peninsula to supply the saw-mills of the state for more than six months. It should be remembered, however, as Mr. Little points out, that there are still left gleanings from third or fourth cut burnt-over stump-lands which produce grades of lumber of very inferior quality, some Red Pine and some inferior Hemlock, which may keep the mills running for a short time.

Mr. Little then assumes that it is fair to suppose that the census estimates of pine standing in Minnesota, Wisconsin and the upper peninsula of Michigan were as nearly correct as experience has shown those of the lower Michigan peninsula to have been, and, taking the census figures of 55,170,000,000 and deducting the amount which has been cut during the last ten years, 37,451,341,338 feet—the figures recently prepared by the *North-western Lumberman*—he finds only about 20,000,000,000 feet standing in the

three states, from which must be deducted the cut of last winter, rather more than 8,000,000,000, leaving a little over two years' supply of standing pine in the whole of the north-west.

Correct estimates of standing timber are exceedingly difficult to make and to verify, but by a system of averages extending over very large areas comparatively accurate results can be obtained, and it is not probable that the figures given above vary very far from the truth. They are not needed, however, to prove that the time is at hand when the north-western states will cease to be great lumber producers. This is abundantly shown by the fact that the most intelligent lumbermen of that region have for several years been engaged in securing great bodies of Pine-timber in the southern states, and of Spruce and Redwood on the Pacific coast. The increased number of destructive fires in saw-mills all through the north-western states, which have been noticed during the last two or three years, is another infallible sign that their business is approaching the end.

There is no hope that these great forests, which have been wasted as forests have never been wasted before, will ever be reproduced. Their end finishes the prosperity of a large section of the country and marks a period of folly and extravagance which seems, as we look back on it, simply incredible. And yet these forests, if they had not been called upon to yield annually more than their natural yearly increase, and if they had not been wasted by needless fires, might have been productive forever, and insured permanent wealth and prosperity where ruin now stares the community in the face. National calamities like the extermination of our Pine-forests are slow in making themselves felt, and the closing of a saw-mill and the ruin and abandonment of a town have, at first perhaps, only local significance. In the end, however, the country wakes up to the fact that a few men have made themselves enormously rich, and that nothing is left but blackened stumps and barren soil to show where once forests existed; and that one of the principal sources of national wealth has gone forever. The exhaustion of the copper and iron ores of Michigan would be a far less serious blow to the prosperity of that state and of the country at large than the destruction of her forests of Pine, and yet for ten years the American people, fairly warned of what was coming, have sat quietly by and looked with barely a word of protest against the extermination of the forests in every part of the country.

The Major Oak.

THE "Major Oak" (see p. 263) is in the best state of preservation of any of the very old Oaks for which Sherwood Forest, in England, is famous; and it is one of the noblest, most vigorous and best preserved of the old historical trees of Europe. It is believed to be one of the oldest trees in England. Beneath its spreading branches King John may well have reposed six hundred years ago, after the fatigues of the chase. Robin Hood and his merry men must have known it well. Since this tree grew to goodly size, great things have happened in the world—the Crusades, the War of the Roses, the discovery of the New World; it has seen the monarchy of England go down before Cromwell and the Covenanters, its restoration and the final fall of the Stuarts, the advent of Protestantism, the birth of science, and all the growth and development of the last two hundred years which have made the greater Britain of the nineteenth century. Here it has stood, stretching out its sturdy arms while the centuries rolled by. Think what England was when the acorn from which this tree has grown dropped to the ground, and then consider what it is to-day! Think what this tree has seen and survived, and it will not be found easy to contemplate it except with awe and veneration. In all England there is not one other thing which has changed so little in the past five hundred years; unless, indeed, it be some other Oak-tree or some of those ancient Yews which, in

England, are more venerable and more unchanging even than the Oaks themselves.

Our portrait is interesting, too, for it shows the habit and appearance of a very old and well preserved European Oak, which our readers will be able to compare with the old Oaks which are found occasionally in this country, although we can hardly hope to match the "Major Oak" with an Oak of equal size in the northern states. There are, however, Live Oaks in the south and in California which exceed it considerably in girth of trunk and spread of branches. The "Major Oak" has always had, fortunately, room enough to grow in, and it is in a soil which is capable of producing large and long-lived trees. The trunk measures thirty-two feet in circumference just above the roots; five feet above the ground it girths thirty feet; the branches have a spread two hundred and forty feet across; numerous roots spread out, partly above the surface of the ground, for a distance of thirty feet from the trunk. The foliage is healthy and abundant, and shows that the tree is still in excellent condition, although the trunk has been hollow from time immemorial. The cavity is now seven feet in diameter and ten feet high.

The "Major Oak" stands in that part of Sherwood Forest which is known as "Birkland," on account of the presence of large numbers of Birch-trees growing among the Oaks. It is not very far from the village of Edwinstowe, outside of Thorsby Park, and on the property of the Duke of Portland.

Forestry and Economics.

AS a subject for economical discussion, forestry was hardly thought of in this country twenty years ago, but now one can hardly read a book or an article which treats in a broad way any question of economic science without finding the present state and future prospects of our forests used to illustrate or enforce the argument. Professor H. C. Adams, of Michigan and Cornell Universities, in his masterly financial treatise, "Public Debts," has this to say:

"It is an historical rule of wide application, that as countries become more populous and the social and industrial relations more complex, the functions of government must necessarily extend to continually new objects. This rule holds good now and in this country, and, in consequence, the question of the residence of new powers becomes more important year by year. Consider, as a simple illustration, the increasing necessity for care of the forests. The frequent recurrence of floods; the more rapid and marked alternation of drought and wet; the progress of farming toward the exhaustion of lands; all point clearly to the fact that the people of this country must soon turn their attention to the culture of trees. But this is a line of enterprise that individuals will not enter upon, because the returns in dividends are too remote from the first investment. It is a legitimate sphere for the employment of public credit, and the only remaining question is: Shall the enterprise be undertaken by the central government or by the local governments?"

In an article on the fall of the rate of interest, especially on securities of the best class, in a recent number of the *Popular Science Monthly*, George Iles says: "Does not cheap and abundant capital make it possible to conserve the Adirondacks as a state park, and as the source of the principal rivers of New York, and to establish a national system of afforestation?" The drift of Mr. Iles' argument is that while the rate of interest remained high there was no inducement to invest capital in an enterprise from which the return was so remote and so moderate. But the present rate of interest and its probable reduction to still lower figures make it necessary for capitalists to seek investments which would hardly have been considered a few years ago. The careful management of forest-property will yield an assured income and the time is at hand when it will offer fair attractions as compared with other fields of enterprise.

"A park is Nature made more beautiful, a garden is an enlargement of the house. Here should be convenience, decoration, nice care, and as much elegance as the owner's means will allow. The turf should seem a soft carpet bedecked with flowers; here should be found the rarest and most beautiful foreign plants, strange animals, birds of bright plumage, gay garden seats, refreshing fountains, cool shadows in thick-planted walks."—*Pückler-Muskau*, 1834.

Horticultural Education.

IT is not strange that there should still be those who question the value of a special education for the horticulturist. Similar doubts were once held concerning education in general, and they have arisen with each new enlargement or extension of educational methods; in fact, they have been dispelled only when experience has proved them groundless. These doubts no longer exist in regard to those technical subjects which were first taught in colleges; but college training in horticulture is of such recent date that it has enjoyed slender opportunity to prove its value. All analogy, however, insists that its results must be good. Much horticultural instruction is, no doubt, incompetent, and all of it is certainly incomplete; but the subject is capable of elucidation and application to the student. Teachers are largely self-taught, even in elementary principles, and lack the breadth of view which enables them to epitomize and generalize; a coming generation of teachers, starting with fundamental knowledge and with enthusiasm, must reap great harvests. Most of our teachers have had little practical experience, both for the reason that they are largely young men and from the fact that no institution yet exists in the country where diversity of good practice together with mental training can be secured. This much I have said by way of apology for what horticultural teaching has not accomplished; but the faults are not vital, but wholly incidental to new ventures.

Much of the disaffection concerning college training comes from a misconception of the relation which education bears to the man. Education does not make the man; it only influences him. Education builds upon the mental quality of the student, and that original quality largely determines the value which an education possesses. This fact is illustrated to every teacher who sees students going out from his instruction; one makes his mark, while his seat-mate, with equal facilities, accomplishes little. But this fact is not a disparagement of education, for it is no doubt true that both are better for their training. But whether the education pays its cost, depends upon the industry and faithfulness of its possessor. Education is simply capital invested; and no two investments are of equal value to their owners.

Disaffection is due also to the fact that a special education is commonly confounded with a trade. It is the aim of our modern technical trainings to attain both these ends, but they are not necessarily correlative. In fact, just here is where the present widespread discussion of horticultural education turns. The "rule o' thumb" should be learned before one enters college; it should be a part of a boy's bringing up. Or, if he has not had the proper bringing up, he must attain this simple handicraft as an auxiliary to his education; and it usually happens that our colleges are not sufficiently equipped with apparatus and instructors to give adequate instruction in all these directions. The teachers of horticulture all exercise the greatest care that instruction in handiwork shall be prominent, and this is essential, not so much, however, to develop skill in handicraft as a continual illustration of the interdependence of precept and example. But it is too much to expect that a youth whose mind is reaching eagerly for knowledge should acquire in the detached hours of a two or four years' training what an apprentice, who does little mental work, is expected to acquire in four or more years of steady application. Yet many writers seem to expect even more than this. In other words, a student should not be sent to college for the purpose of learning how to hold a plow, how to make a cutting or how to pot a plant. Hercules should not be called upon until there is something heavy to lift.

But, as a matter of fact, many young men are sent to college for this very purpose. I asked a class of sixty-four students how many had ever seen the operation of budding performed. One raised his hand. The other sixty-three were given instruction in budding so far as one man with less than two hours a day to devote to the labor could instruct such a number before the bark upon the Peach-trees "set." And many of them were the sons of fruit-growers! I often wonder how many of them derived any profit from the operation!

It is too much to expect that the student is to acquire a full trade in college. College work broadens him, strengthens him, inspires him; and the knowledge, which is everywhere incidental to his course, is always of practical use to him. If he does not learn how to bud while in college, he ought to be able to acquire the art quicker and grasp it more intelligently than if he had not had the training. Some one remarks that a college training does not teach a youth how to handle some new plant, that it does not enable him at once to discern its requirements. This is certainly true, but training does not

make him less able to discern them. Such matters are wholly empirical, and must be learned by the doing. But I should expect the educated young man to discern more readily than another, or, at least, to acquire a more complete knowledge of the matter, if both had possessed equal powers to start with. The illustration, however, is trivial. A college training is not meant to enable a youth to drive a nail without danger of pounding his fingers.

Comparisons are often drawn between graduates and ignorant men who are skilled in some particular work. Such comparisons are fallacious because they contrast things wholly unlike—mental training and mere handicraft. A graduate may not have had opportunities for learning that particular thing, but there are a hundred other things which he can do better than the workman. There are thousands of men who are more skillful in certain things than any professor of horticulture. There are thousands of men on the streets of Paris who can speak French more fluently than many professors of language.

But, after all, shall we hire college men for our gardeners? That depends upon what a gardener is wanted to do and know. If you want him simply to grow Lettuce, let the college man alone, for he has ambitions above you. If you want him to manage your place with tact and judgment, and grow Lettuce at the same time, you may find him better. If you find some uneducated man to suit, you will soon hear yourself remarking, "What a pity that man could not have had an education!" for you will feel that education ought to have made him still better. I know of many college-bred men who make the best of farmers and gardeners. And I know of a few who are failures; I often wonder what would have become of them if they had known less! But this whole comparison of the graduate with the apprentice is invidious. A man is valuable simply for what he is, not for what has made him.

Cornell University.

L. H. Bailey.

Plans for Small Places.

PLANS of four small places are herewith presented (see page 261), each showing exercise of judgment in the adjustment of buildings, roads and walks to special local circumstances. The problem in each case was to so manage the constructions necessary to convenience as to mar as little as possible whatever natural landscape advantages the situation possessed.

In the case of No. 1, outlooks to the west and south were limited by buildings and trees on the opposite sides of the streets. By placing the house, stables and yards near the streets, room was made for a symmetrical and comparatively spacious and sheltered lawn to the eastward. The more important rooms of the house look over a terrace upon this lawn.

In the second example the view northward toward the street is limited, while to the southward a superb distant prospect will be permanently commanded. The object has been to so place the stable, and the stable, kitchen and laundry yards, that they would not break in upon the southern outlook, while leaving the largest space of unbroken lawn in direct view from the principal rooms that could be reconciled with convenience. Walls overgrown with creepers keep the yards out of sight from the approach road.

The third case is that of a narrow lot between two streets not parallel one with the other. There is no distant prospect to be considered; but, again, the leading motive of the plan is to obtain as much unbroken lawn space as practicable, especially on the sheltered south side. The kitchen, kitchen-yard, stable and stable-yard, and the carriage-approach, are worked snugly into the north-west quarter of the place, and the principal rooms look upon pleasing, though confined, domestic, local scenes to the north-east and to the south.

The fourth sketch illustrates a cramped, tilted and otherwise difficult situation near the top of a steep hill, the lot being bounded on three sides by public streets. The position is elevated and a fine distant view will be under permanent command to the south-east. From the point A to the point B there is a continuous descent of eighteen feet. The main floor of the house is two feet below the street on the south side and ten feet above the street on the north side. The street on the south side is carried on a retaining wall of field stone built very roughly, without mortar, spreading toward the base and furnished with numerous pockets and deep crevices filled with leaf mould. Opposite the more important windows of the house the parapet of this wall is ten feet or more above the natural surface of the ground.

Between the base of the retaining wall and the house there is a slight ravine, providing for surface drainage, the north side of which constitutes a bank covering the high foundation

walls of the house. A walk, leading from the street on the south to the house, crosses this ravine upon an arch of field stone connecting with the stone of the retaining wall. Mosses, fern and creepers dress all this stone work, and the banks of the ravine are planted with shrubbery that will nowhere grow so high as to obstruct the outlook from the windows. Windows of the three principal rooms of the ground floor and the little terrace shown on the diagram all command the important view to the south-east. The upper windows look over the stable.

All these plans have been carried out with satisfactory results, and a more detailed account of the work on some of them may be given in a subsequent paper.

Brookline, Mass.

F. L. O.

[It is to be remembered that these diagrams illustrate simply the solution of the fundamental problems presented in each case. And yet the determination of the framework of the design is, of course, a matter of controlling importance, and the special training of the landscape-architect is needed at this point, if it is required at any. If his assistance is not invited until after the house has been located and perhaps built, he may find it impossible by the most skillful after-treatment to correct the fatal mistakes already made.—Ed.]

Notes on North American Trees.—XVII.

THE West Indian Birch, or Gum Elemi, one of the trees of tropical America which reach the shores of south Florida, has long been known to botanists as *Bursera gummifera*, the name given to it by Jacquin in his "Selectarum Stirpium Americanum Historia," published in Vienna in 1763, who there established his genus *Bursera*, or *Burseria*, as he wrote it, for this plant. It was well known to earlier botanical writers like Hermann, Plukenet, Browne, Sloane and Catesby, having been one of the first of the American trees to attract the attention of Europeans, who fancied that its resinous juices possessed special medical virtues. It was this plant, probably, which Linnæus, in his "Materia Medica" published in 1749, called *Simaruba*, considering it, perhaps, identical with the *Simarouba* of the Caribs and the inhabitants of Guinea (the *Simaruba amara* of Aublet), as not many years later he refers the *Simaruba* of that work to the *Bursera* of Jacquin. But previously to the publication of Jacquin's genus, Linnæus had described our plant in the first edition of his "Species Plantarum," published in 1753, as *Pistacia Simaruba*, and it was not until the publication, in 1762, of the second edition of the "Species" that he adopted Jacquin's genus, changing Jacquin's orthography to *Bursera*.

It may be mentioned in parenthesis that curiously enough the published date of Jacquin's work is 1763, and that that of the second edition of Linnæus' "Species" is 1762; still Linnæus quotes there correctly Jacquin's figure of *Bursera gummifera*, published a year later. The date of the publication of one of these books as printed must be wrong, therefore, unless, as is more probable, Jacquin submitted his figure and description of *Bursera* to Linnæus before they were actually published. This, however, is unimportant, and what I want to call attention to is the fact that the authors who have written of our *Bursera* since Linnæus have overlooked the description in the first edition of the "Species Plantarum," and the fact that *Simaruba* is the earliest specific name of the species, antedating by ten years Jacquin's name; and that the principle of using the earliest Linnæan specific name being adopted, our plant must become *Bursera Simaruba*. There can be no doubt concerning the identity of the plant Linnæus described as *Pistacia Simaruba*, for he quotes under his description the unmistakable figures of Sloane in the "Natural History of Jamaica," and of Catesby in the "Natural History of Carolina," while in the second edition of the "Species" he quotes as a synonym of *Bursera gummifera* his *Pistacia Simaruba* of the first edition. The case is a perfectly clear one, therefore, and the change of name is unavoidable if the principle, which seems correct, is adopted.

C. S. Sargent.

Foreign Correspondence.

London Letter.

MAY has brought sunshine with the showers which ought to have come in April, and the gardens are now delightful. Cherries, Plums, Pears, Barberries, Magnolias, American Azaleas, Laburnums and even Horse-Chestnuts are in all their flowery glory, beautiful to look upon and deliciously fragrant. In spite of a dry April and undue prevalence of east wind, the trees and shrubs are as luxuriant in new leaf and flower as one could wish. On the ground beneath the trees there are carpets of Bluebells extending as far as the eye can see in many places. Nothing could be more charming than the rich blue of the flowers of this plant used for covering naked places under trees or to give color to long sweeps of green lawn. Anemones of various kinds, including the brilliant scarlet *A. fulgens*, are largely employed for purposes of this kind at Kew. The effect of what is termed a natural arrangement of such plants is infinitely better than anything produced by planting them in formal beds. Tulips also are largely used for spring effect, and they may be made to add a wonderful amount of color and life to large gardens by planting them in positions where they can be seen at a distance. Arranged in set beds with an attempt at color design Tulips are stiff as ninepins and almost as ugly; but used with judgment and not too freely they are most effective. On a sloping, grassy bank on the sunny side of what is called the Wild Garden, a large number of Tulips have been planted in the grass, irregularly. The flowers amid the grass as tall as they are have a charming effect. Besides the best of the garden Tulips, including "Parrots" and "Darwins," some of the most beautiful of the species are largely planted at Kew. *T. Greigii*, grandest of all Tulips, its large, elegant cups of the richest poppy scarlet, ought to become as popular in the garden as "Emperor" and "Empress" Daffodils. It is a native of Turkistan, comparatively new, and as easy to cultivate as any Potter or Duc van Thol. *T. retroflexa* has tall stalks and a cup formed of long, pointed segments which are slightly twisted and recurved, whilst in color they are canary-yellow. *T. elegans* is similar in form to the last named, but deep crimson in color. *T. acuminata* is another of the same stamp, but the flowers are yellow with a tinge of red on the ends of the segments. *T. Kolpakowskiana* has a regular cup-shaped flower, rich cardinal in color, with a black eye-like blotch at the bottom of the cup.

CARAGUATA ANGUSTIFOLIA is one of the prettiest of the smaller Bromeliads. It forms a compact tuft of short stems and short, narrow, dark green leaves, from amongst which the flower spikes spring. These are five inches long, curved, as thick as a man's finger at the base, thickening upward, owing to the overlapping of the boat-shaped bracts, which are brilliant scarlet. The flowers are about two inches long and colored rich yellow. Several plants of it are now in flower at Kew, one with four spikes, although the plant is not a foot through, and nothing could be prettier. The species is a native of the Andes of New Granada, from whence it was introduced by the Messrs. Veitch, and distributed from their nursery in 1886. Most of the Caraguatas have large brightly-colored flowers and bracts, and they are easy to cultivate. To any one in search of a distinct, beautiful, little flowering plant I would strongly recommend *C. angustifolia*.

SOLANUM WENDLANDII.—This is by far the handsomest in flower of all the Solanums known to me; indeed, it is so superior a plant that one almost wishes it were called by some other name than Solanum. It is a stout growing climber, with fleshy, tubercled stems, large, entire or laciniated leaves, and enormous trusses of large, purplish blue flowers. A plant in one of the stoves at Kew has a stem thirty feet long, with short lateral branches, from which hang the flowers, the largest truss of which measures over a foot through. The flowers are not fugacious, as those of most Solanums are, and the plant will continue to develop bloom all the summer through. For this grand species we are indebted to Herr Wendland, of Hanover, who introduced it from Costa Rica. It revels in rich soil and plenty of water when growing, but during winter it should be kept dry. For large stoves there are not many plants that equal this as a flowering climber. There is a figure of it in the *Botanical Magazine*, t. 6914.

RHODODENDRON KEWENSE.—This is a hybrid obtained at Kew by crossing *R. Hookeri* with *R. Aucklandia*, where it flowered for the first time in 1878. A plant of it now flowering in a position where it has been slightly protected in frosty weather is a magnificent picture. The flowers are in loose, erect heads, about ten in each head. When in bud they are a bright rose-crimson; when fully expanded they are bluish white, cup-shaped

Fig. 39.—Outline Plans of Four Small Places.—See page 259.

and three inches across. The young leaves are subtended by large crimson bracts, and the effect of the whole is a rich glow. The plant is six feet high and nearly the same through, and it bears about fifty heads of bloom. It is the finest of all the hybrids hitherto raised from the Himalayan *Rhododendrons*.

R. AUCKLANDIÆ is also now finely in flower in the Winter Garden. There are few more noble greenhouse plants than this. It requires plenty of space, never flowering until it is eight or ten feet high, and it ought to be planted out. The flowers are in loose, erect heads, and each flower is at least six inches in diameter, saucer-shaped, and pure snow white. This species is as grand among *Rhododendrons* as *Magnolia grandifolia* is among its kind.

PTERIS ENSIFORMIS, VAR. *VICTORIÆ*.—This is one of Mr. Bull's new introductions from the East Indies, and it is so distinct in character, so graceful in habit and pretty in variegation

that it is certain to become universally popular as a decorative Fern. It belongs to the same group as the well known *P. cretica* and *P. serrulata*, but is distinguished by the tallness and erect habit of its fertile fronds, the pinnæ of which are very narrow. The barren fronds form a compact rosette and are broad in the pinnæ. The whole plant is green, conspicuously mottled and margined with white. Mr. Bull will, I believe, include this Fern in his list of new plants for sale this year.

STREPTOCARPUS DUNNII.—Of the many extraordinary plants introduced into cultivation from South Africa this is one of the most remarkable. Its solitary leaf sprawls along the ground like a huge Rhubarb leaf minus the stalk, whilst from its base spring crowded racemes of tubular brick-red flowers, the largest racemes containing as many as a hundred flowers. In the house devoted to succulent plants at Kew there is a row of plants of this *Streptocarpus*, numbering about fifty, and

they are now in flower, presenting a picture of the strangest character. Seeds are produced freely by cultivated plants, and the seedlings grow into full size in a year. The leaves are a yard long and about half as wide.

Strikes are the order of the day in England, and the discontent which leads up to them has affected the market-garden laborers of West Middlesex. Last week about 500 of them paraded the streets and demonstrated in Hyde Park. Leaving their work at this time of the year they have seriously crippled the masters, and unless an arrangement is soon arrived at permanent harm may be the outcome. From the men's standpoint, indeed from a common sense standpoint, the men's demands are fair and reasonable, and one hopes they may be granted. In America it will appear strange, perhaps, that men who are adepts in the work of growing flowers, fruit and vegetables for the London market, which means that they are grown as well as they can be grown; men who cannot be called mere laborers, because the work they perform requires skill and experience as well as endurance; that such men should have to strike to obtain wages of fourpence ha'penny an hour. This is the men's side. From the masters' side it has to be admitted that the price they can afford to pay for labor is regulated by the market, which is open to the produce of all countries. Put, say, ten per cent. upon the cost of the production of the market-gardens in England and probably the English produce will be beaten by the foreign. The lot of the market-gardener of London is not by any means an easy one.

CYTISUS ADAMI.—In the Coombe Wood Nursery of Messrs. Veitch, an interesting experiment is being made with a view to testing the theory that this *Cytisus* is a graft hybrid between *C. purpureus* and *C. Laburnum*. A row of plants of the last named have been grafted with *C. purpureus* and the results will be carefully watched. Messrs. Veitch have undertaken this experiment at the request of Dr. Romanes, an eminent English naturalist and a fellow-worker with Mr. Darwin. If the theory with regard to *C. Adami* is correct, it is strange that amongst the millions upon millions of grafted plants this is the only case of the kind that has occurred.

Orchard Experiences.—V.

THE "education" of an orchard (in the fundamental sense of the word) is the nicest and most important portion of the orchardist's work, and that which will both test and demonstrate his knowledge. A man who can take an orchard of even twenty varieties of Apples and train each one in accordance with its habit of growth into a perfect tree, is a worthy candidate for the highest degree of any horticultural college. Such work must begin with the young tree. It ought to begin in the nursery. It is a difficult task at the best, and most difficult of all with varieties unfamiliar to the operator.

There is an immense diversity of growth among different varieties. Some require almost no pruning at all, having but small tendency to multiply their branches; while there are other sorts very close-budded, and not a dormant bud amongst them all. Years ago a now eminent botanist suggested to me that the branching of an Apple-tree should be based upon its phyllotaxy—the side branches to be five in number, growing in an ascending spiral around a central trunk. I could never make this system work in practice, except with an occasional seedling, usually a Siberian Crab.

If Nature were sufficiently compliant I would start the head of every standard Apple-tree with but three main branches; but a danger in attempting this is that it may end in getting but two. Certainly, the main branches must be far enough apart in the beginning never to become opposite or nearly opposite. They ought to stand in some symmetrical order, so as to make an evenly balanced head, since a tree will always tend to lean toward its heavier side. In northern New England all orchards, the trees of which were set perpendicular, will in fifteen years lean, and most of their branches will point, toward the north-east. With a view to obviate this, many now lean the trees in planting toward the south-west, from whence are the prevailing winds during the period of active growth. These winds will, in the end, win the battle, though the contest is thus somewhat prolonged.

That pruning is best which keeps the tree in proper form with the removal of the least wood. "Penknife pruning" is strongly advised, and is the ideal method; but it demands eternal vigilance. Some varieties bear the removal of quite large limbs without much apparent injury, while with others the taking away of a limb an inch through will leave a wound that will never heal, soon making the trunk rotten and

ruining the tree. It has been often advised to cover all such wounds with some sort of composition or cement, or to paint them with a thick, ochreous paint. This does some good, but not much. If the variety is thoroughly hardy in the climate where it is growing a wound not exceeding an inch across will grow over in two seasons. If not hardy, the attempt to heal will be defeated by the winter-killing of the new growth, and the wound will tend to enlarge rather than heal, the tree becoming "black-hearted," breaking down and dying.

What is this disease of "black heart," about which so much has been written? It is simply the killing of the weakly vitalized heart-wood by low winter temperature. This takes place with different varieties at different temperatures. Is it the temperature at which the sap freezes, as Mr. Meehan has taught? I do not know; but this I do know, that nearly every variety of southern New England and the middle states becomes black-hearted in northern New England and Canada. If no wounds are made that will not heal in one season, such trees, "hardy, but not iron-clad," may live and bear much fruit before dying; but at last they perish when an over-crop breaks down the weakened branches or a phenomenally cold winter comes along.

Even with the most thorough iron-clads, I would paint and repaint every season, until healed, all wounds too large to heal in one or two seasons. From my experimental plantings, begun twenty-four years ago, I have been removing year by year a good many trees that have proved failures, or for overcrowding. Using the wood of these trees in my office stove, I have had a good chance to study their morbid anatomy and to trace the effects of cold and of pruning upon them. In every case of black heart from pruning, it has been easy to trace the course of decay inward and downward from the point of removal, and the lateral spread of the fungous disease which accompanies it, until the whole trunk is infected. There is no preventing or stopping this decay in any of the tender varieties. Once it begins, the destruction of the tree is sure. But in the "iron-clads," and especially in the Russian varieties, even when the wounds are large and have not healed over for several years, there is not a particle of decay or any fungoid infection. The woody fibres continuous with the severed branches show a changed color and seem destitute of life; but this wood is dry, hard and elastic, and the change does not extend to the contiguous wood. The wounds heal over perfectly, and there are no signs that the tree is not quite as healthy as others of the same variety that have never lost a limb.

Newport, Vt.

T. H. Hoskins.

Notes on Shrubs.

IN GARDEN AND FOREST for May 7th Professor J. L. Budd writes of the hardiness of *Prunus tomentosa* at Ames, Iowa. This little Cherry has usually proved perfectly hardy and borne an abundance of flowers and considerable fruit at the Arboretum, but this spring a large proportion of the buds and even some of the branches were destroyed, the injury being most severe to those plants on low, rich soil. This is a pretty little shrub with a broad spreading habit, specimens in the Arboretum attaining a height of five or six feet and resembling a very large Currant bush. It is one of the earliest of the genus to bloom, and when in good condition the branches are covered with medium sized white flowers, which usually have a more or less pinkish color. The flower stalks are so short that the blossoms appear almost sessile. The ripe fruit is of a light cherry-red color and has an agreeable flavor. It is a small Cherry and contains a large stone. Dr. Bretschneider collected seed of this plant in the mountains about Pekin, China, and as a rule it may be counted hardy in every way.

Among the four or five species of eastern North American Plums there is none so hardy or so showy when in blossom as the Wild Red Plum (*Prunus Americana*). In regard to hardiness it is what the gardeners term "iron-clad," and is found in the open woods far north in Canada. The vigor and endurance of the species in Manitoba and other equally trying regions where it is indigenous have in recent years caused some attention to be given to its cultivation and the improvement of the quality of its fruit. The fruit, which is either red, orange or yellow, varies much in size on different trees when growing wild. It is often of a pleasant taste and is sold in some northern markets. At the Arboretum the showy snow-white blossoms of plants from the north and north-west appear before the leaves during the first week of May and continue for seven or eight days, but it is noticeable that plants from Ohio are nearly a week later in flowering. When varieties of *Prunus domestica* and other cultivated Plums are very seriously affected by "black knot," the Wild Red Plum is often

remarkable for being free from it. As a stock upon which to graft many other species and varieties of the same genus this is one of the best. The little Beach Plum (*P. maritima*) comes into bloom as the last flowers of the Wild Red Plum fade, but although it blooms as freely, the whole aspect is different. The flowers lack the fleecy whiteness of the first species and as the flower-stalks are short they appear clustered on the branches.

Three or four species of flowering Currants attract much attention at this season. Of these *Ribes sanguineum* is unquestionably the most beautiful, although unfortunately the least hardy. In the climate of Boston it is necessary, if the plants are to do well, to give them more or less protection according to the situation in which they are placed. Although long known it is surprising that this beautiful flowering shrub is yet familiar to very few people. The plants grow well in any ordinary, moderately dry, warm soil. The racemes of bright, rose-red flowers are the only attraction of the plant, for neither the foliage nor fruit have any peculiar ornamental or economical value. The ripe fruit is small, black, tough, dry and bitter. The odor of the flowers and other parts of the plant very much resembles that of the cultivated European

so regularly attack the common red Currants and Gooseberries.

Ribes cereum is another rarely cultivated Currant from the western part of the continent, which, although not conspicuous nor large growing like the species already mentioned, has flowers of much interest and beauty. The blossoms, much hidden by the leaves, drooping and few on a raceme, are tubular and from a third to nearly half an inch in length, and of a pretty pinkish white color with a waxy appearance. The flowers of *Ribes aureum* and *R. cereum* are particularly rich in nectar and are much visited by long-tongued bees, and the long tubular calyxes of *R. aureum* are also regularly punctured by the mischievous Carpenter Bee (*Xylocopa virginica*), which is usually mistaken for a humble bee.

The first flowers in the paniced cymes of the early Red-berried Elder (*Sambucus racemosa*) usually open about the end of the first week in May, and continue for ten or twelve days. The flowers on different plants vary from greenish to pure white, and often have a reddish tinge, and when in full bloom they add much to the effectiveness of the shrubbery. Again at the end of June the ripe, bright red fruit is very conspicuous,

The Major Oak, Sherwood Forest.—See page 258.

Black Currant, though less rank. In cultivation there are varieties with flowers of various shades of color from deep red to almost white. As it grows at the Arboretum this species does not develop such tall and stout stems as the bright yellow flowered Missouri Currant (*R. aureum*) so common in cultivation. The flowers of the last species are spicily fragrant, and no part of the plant has much of the odor of the Black Currant, which is disagreeable to so many people.

There seems to be no question of the hardiness of this species even much further north, and it thrives fairly well in poor soils and in shady places where most other related species would languish. The fruit when ripe has a peculiar sweetish but not agreeable flavor. It is black or bluish black, and sometimes quite large, although exceedingly variable in size, and the berries are few on the racemes. These two western species are said to have been the parents of the hybrid *R. Gordonianum*, which in foliage and flower most resembles *R. sanguineum*. The hybrid has the erect, stout-growing habit of *R. aureum* and it also partakes of its hardiness. The flowers are practically odorless, and, as in the case of many hybrids, they do not appear to be followed by fruit. None of the preceding species are touched by the defoliating larvæ of saw-flies which

just at the time that the common Elder (*S. Canadensis*) begins to be showy with its large flat cymes of white flowers. There is a natural cut-leaved variety of the Red-berried Elder, which is likely to become more commonly seen in gardens.

Most of our native, as well as the foreign Alders, are characterized by very early spring blooming, but the Green Alder (*Alnus viridis*), a native of the northern and mountainous parts of eastern America, does not ripen its pollen until the blossoms appear on the Red-berried Elder. This little Alder only grows from three to eight feet high, and is the last of the genus to develop foliage in spring, the leaves not appearing until the flowering of the catkins. The sterile catkins are very handsome, being sometimes from three to four inches long and quite thick. When fully open the flowers appear light yellowish green under the shelter of the rich brown bracts. The sterile catkins are exposed all winter, while the small fertile ones are protected within large, reddish brown, scaly buds, thus differing from other common species, which have all the catkins exposed in winter.

The plants grow well in cultivation at the Arboretum and the foliage in summer is a handsome dark green.

Arnold Arboretum.

J. G. F.

Spring Flowering Iris.

TWO of the prettiest of all the spring Iris lately in flower are *Iris Persica* and *I. Rosenbachiana*. Other kinds now past are *Iris reticulata cyanea*, I. "J. G. Nelson," the bright little yellow *I. Bornmüller*, and we have had flowers of *Iris stylosa alba*, and the "Snake's-head," or "Widow Iris," *I. tuberosa*, a fragile little flower that has a sombre appearance, suggestive of apple-green satin and black velvet. The typical *Iris stylosa* of Algeria has yielded odd blooms ever since Christmas, and quite lately a large tuft of it, covered by a frame light elevated on posts, gave us quite a dainty crop of its soft lilac buds and blossoms. The typical *Iris reticulata* is after all one of the sweetest and most useful of all the spring blooming kinds, and has become luxuriant since Mr. Bedford, of Straffan, taught us the right way to grow it in peat, sandstone grit and cocoa-nut fibre refuse. The rich violet-blue flowers are deliciously scented, and our friends and visitors have been quite delighted with them this season.

One of my pet Irises is the old *I. Persica*, which, apart from its beauty, is quite of historical interest, since it forms No. 1 of that splendid series of plates issued in the *Botanical Magazine*. It was formerly the fashion to grow its roots in water-glasses, as is now occasionally practiced with Hyacinths, but in a deep sandy peat-bed the bulbs are far more robust, and more permanently healthy. The flowers of this species are of a delicate blue tint, verging to green, the hue of a thrush's egg, for example, and there is a velvety blotch on each of the "falls" around the end of the rich orange crest, and some dark dots and markings help to emphasize the satin-like delicacy of the petaloid styles, or standards, as Iris-lovers call them.

One of the most robust of all the newer species seems to be *I. Rosenbachiana*, which bears a bold little flower, similar in shape to that of *I. Persica*, but of a smoky lilac color, having a rich dark blotch on the falls, lit up by a vivid orange ridge or crest, on a nearly white ground. It is strong and beautiful, and promises to be quite an addition to a very beautiful group. So far as I have tried them, all the species and varieties of Iris are quite delightfully adapted for cutting, provided that they be cut in the full grown bud stage, and not allowed to open on the plant. *Iris reticulata* and all its forms, *I. stylosa* in variety, *I. Rosenbachiana*, *I. Persica* and all the great Flag Irises yield exquisite blooms as cut in the bud state and opened in water in-doors. Certainly if allowed to expand on the plants, or to remain long open in the open air, nearly all Irises are fragile and fugacious enough, and one might paraphrase old Robert Herrick, who lamented that the Daffodils "wasted away too soon."—*F. W. Burbidge in the Gardeners' Chronicle*.

Notes on American Plants.

THE California Pitcher-plant (*Darlingtonia Californica*) is now in flower here. Our plants were set in a moist place on the south side of a stone wall, which perhaps accounts for their blooming so early. The almost naked scape bearing the single flower is fifteen to twenty inches high, curving at the top, so that the flower is pendent or nodding, as is that of *Sarracenia purpurea*. The narrow, greenish straw-colored sepals are an inch and a half long. The purplish petals are an inch long by half as wide, slightly streaked with yellow, and only partially hidden by the longer sepals. In fully developed plants the long and peculiar pitcher-shaped leaves are very interesting. It is seldom that really fine specimens of this plant can be had from collectors, but we have seen such with beautiful long leaves over a foot in length. It is generally considered a difficult plant to grow, yet, I think, if in the right place, and with a protection of leaves in winter, it can be grown and flowered with success. It seems to prefer a black peaty soil. Ours, now set in sand, do not show health as we have seen it in decayed peat. In a boggy situation, set in peat unmixed with sand or gravel, we believe it would thrive.

Uvularia perfoliata, one of the Bellworts now in flower, is about a foot high, with light yellow or cream-colored pendent flowers, nearly an inch long by a fourth of an inch in diameter, and it has darker foliage than either *U. grandiflora* or *U. sessilifolia*. It seems to do best in a fine loamy soil. We have never succeeded with it in a heavy soil. It needs to be set in early autumn in order to flower freely the following spring.

The Scarlet-painted Cup (*Castilleja coccinea*) is a biennial, with a hairy stem and leaves. At the summit around the flower are so-called floral leaves, the upper portions of which are of a beautiful bright scarlet color, more showy than the flower itself. It may be easily grown in moist sandy soil.

Iris cristata, from the southern Alleghanies, which has been mentioned in former numbers of GARDEN AND FOREST, is one of our earliest of this genus, and is certainly for many loca-

tions a valuable plant, forming dense beds of its fresh green foliage, only five inches high, but thick and even, with an abundance of light blue and white flowers an inch and a half wide. If it did not flower at all, its foliage alone would make it worth growing. It will thrive in any well drained soil.

Camassia esculenta, from the Pacific coast, now in flower, grows from ten to twenty inches high, with long grass-like leaves from near the root, and bearing at the top a loose spike of violet-blue flowers, five inches long. The flowers are an inch or more wide and there are from ten to twenty on a spike. These are valuable for cutting. The bulb is easily wintered by protecting with a thin covering of leaves.

A rare and delicate little Primrose is *Primula Mistassinica*, found in only a few locations. At Willoughby Mountain, Vermont, it is quite abundant in places. Its height is from three to nine inches, and it usually bears in a small umbel several pinkish or light purple flowers scarcely half an inch wide. Its natural home is in the moist soil at the foot of wet rocks. It can easily be grown in a cool and shady place, in clay or gravelly loam, and will continue to flower from year to year.

Clematis ochroleuca is not a climbing species. It grows from ten to fifteen inches high, bearing numerous pale purple or nearly white flowers, three-fourths of an inch long by half an inch wide. The plant is not a very showy one in flower, but its plume-like fruit is pretty. In its general appearance it much resembles *C. Fremontii*, but the latter is a stronger growing species, with larger leaf and flower. This species has darker flowers, and is a more stocky plant when well established. *C. Douglassii*, of Oregon, is somewhat like the two just mentioned, but its flower is more showy than either, being a dark purple. The foliage is finer and more divided, and the plant is not so tall. All three come into flower at nearly the same season. They do best in open sunlight in light soil, and are interesting both in flower and fruit.

Fritillaria recurva, which has been mentioned in a former number of this paper, is now in bloom, and it is certainly one of the most attractive plants from the Pacific coast. The plant can be grown readily in a light loamy soil, with a thin protection in winter. It blooms early, and its scarlet, lily-like flowers are of long duration, and it will be very useful for cutting.

Southwick, Mass.

F. H. Horsford.

Hardy Plants for Cut Flowers.—VI.

THE best Ranunculus for cutting is the double form of *R. speciosus*. A patch of this variety is now a bright yellow, visible for some distance. This plant has flowers, large and very double, borne on good stout stems, and is far better than any other we have tried. It will succeed in any moist soil; the more wet the soil the better, so long as it is not liable to become sour. *R. speciosus* also increases rapidly and bears division annually. There is also now in bloom the earliest of the Pæonies—*P. paradoxa*. This species always flowers two weeks earlier than any other, and has large, deep rose-colored, single flowers, which are very showy just now, but two weeks hence would be invisible among the other varieties of garden origin; but flowering so early, it is an acquisition to the flower border. The foliage also of *P. paradoxa* is quite distinct from all others in being of a dull glaucous green.

Various kinds of Hemerocallis are also in bud, and the earliest, *H. Dumortieri*, has already opened some of its bright orange colored flowers. *H. Mittendorfiana* will soon follow; also *H. flava*, with lemon-yellow fragrant flowers, and last of all *H. Thunbergii*, which flowers in August, but is similar in color to *H. flava*. These are the four best of the Hemerocallis for cutting. The individual flowers last but one day, but the unopened buds expand in water in succession almost as well as on the plant. There is another Hemerocallis, with finely variegated foliage, known as *H. Kwanso variegata*, which is one of the best of hardy ornamental-leaved plants. It is liable to turn green sometimes, but if the green shoots are taken out when they appear the variegation can be held constant.

The best early herbaceous Anemone is *A. rivularis*. The flowers are pure white, almost as large as those of *A. Japonica*. They begin to open at the end of April, in May they are at their best, but they are produced at intervals all summer, so that this plant has considerable value for the border or for cutting. Many have seen and all have admired the graceful flowers of this, the so-called "Snowdrop Windflower," owing to the way the flowers are borne on the stems. We find *A. rivularis* succeeds admirably in the open border, and intending trying it in half shaded positions in masses, where the effect would be charming. One flower produces seed enough to raise a hundred plants, and these flower the second year, so there is no reason why *A. rivularis* should not be better

known than it is among lovers of heavy plants. The Hybrid Primroses have already been mentioned in GARDEN AND FOREST and it is surprising how little these plants are grown and known. We adopt no other method in winter than the placing of two boards, one on either side of the bed, to collect and retain falling leaves, and these are sufficient protection. The common English Primrose and Cowslip thrive under the same treatment. It should be stated that the bed is under the shade of overhanging trees, for we found that in our sandy soil the plants could not stand the fierce heat of summer. *Primula Sieboldii* is less known than the hybrid kinds, but it is perfectly hardy also, and being deciduous one can apply a top dressing of two inches of manure in fall, through which the young leaves and flower stems will push with vigor in early spring. The great value of *P. Sieboldii* is in the color of its flowers, which are of a deep rosy purple, and when flowering side by side with the hybrid varieties the latter look pale and washed out by comparison. The plant appears in many varieties, but none equal the type for brilliancy of color and stout, erect stems. We always sow all seed that ripens as soon as gathered; it sometimes takes six months to germinate, but the plants will all flower the second year and will show plenty of variation in size and color, and we have raised some of our best from seed saved from our own plants. *P. Sieboldii* throws its flowers well above the foliage on stout stems often a foot high, and these flowers when cut have a very choice appearance, for their color is not common among hardy flowers.

The native *Cypripediums* are now at their best. *C. pubescens* and *C. parviflorum*, with their yellow and brown flowers, are fully expanded, as is also *C. montanum*, a species from Oregon which is perfectly hardy in the east. The prettiest of all is *C. spectabile*, the "Moccasin Flower," and this flowers later than the others. These beautiful Orchids are very easy to grow wherever a shady position can be afforded them, for they dislike sun, and it is safe to say that although among exotic kinds of *Cypripediums* there are many weird and fantastic flowers, none of them can excel in beauty and delicate coloring the pretty native *C. spectabile*. E. O. Orpet.

Seasonable Hints.—The season is now sufficiently advanced to warrant the planting of all tender vegetables. Gardeners who made haste to plant them earlier will find that owing to the cold rains and low temperature of last week no time has been gained. If Egg plants are now set out they should be carefully watched, and if attacked by the Potato beetle should receive a dusting or sprinkling with diluted Paris Green. In planting Lima Beans it is good practice to set the seed eye downwards. The dwarf or bush Limas deserve a fair trial and may be planted about a foot apart in rows two feet apart. Corn fertilized in the hills will get a better start before the warm weather in which it makes the strongest growth. In setting out Tomatoes each plant should have three feet of room and when support is needed three stout stakes should be driven about each plant and about two and a half feet above the ground a barrel hoop should be nailed to them. The Dwarf Champion is of such a stocky habit that it does fairly well without support. Celery plants can now be had of the dealers and if set out at once in a deep, moist soil may be had fit for the table in August. The cultivation should be the same as for a late crop except that boards can be used to better advantage for blanching them than earthing up. Sweet Potatoes will grow best in a sandy warm soil, and placed in this latitude on slightly raised ridges three feet apart and about one foot apart in a row. Succession crops of Peas and Beans may be sown and the seed of Cabbage, Cauliflower and Kohlrabi may be sown for autumn crops.

The Flower Garden.—Plants for summer decoration may all be set out now. Many of them may occupy the beds which have been filled with Dutch bulbs, now done flowering. Hyacinths, Tulips and Narcissus can be bought so cheaply that they are hardly worth the labor of preserving; but if it is desirable to keep them, the best plan is to allow them to remain until the leaves begin to wither. They should be then lifted and set close together on the surface of the ground in a sunny position and covered with an inch or so of soil or sand. In about a fortnight the bulbs will be ripened, when they should be taken up and dried in the sun for a couple of hours and they will then be in proper condition to store away for planting next fall. Shallow cultivation should not be neglected in the flower-beds, for this keeps down weeds and preserves the moisture. Wherever mildew appears the flowers of sulphur should be applied at once.

Bergen, N. J.

P. O.

The Forest.

Forestry in Northern Ohio.

IN this region it would seem that two essential conditions are required for the reproduction of forest-timber. First, a few trees of the kinds that will be most needed in the future must be spared to disseminate their seeds. Second, cattle must be excluded. The case is complicated when birds and rodents destroy the seeds of certain species. In the case of the Magnolia there are sometimes no seedlings near the parent tree, but we are surprised to find them coming up a long distance away, since the seed could not have been carried by the wind. It has been suggested that the blue jay picks the red berries out of the Magnolia fruit or "cucumber," and the nutlets within escape digestion, and are scattered. This is made probable by the young Magnolias we find on the forest-border near corn-fields, places of resort for the jay when corn is ripe. The seeds of the Whitewood (*Liriodendron tulipifera*) are blown by the wind 300 to 400 feet at least, as are those of the Maple and several other trees.

But these essential conditions have been almost wholly neglected. During from sixty to eighty years the young of our forest-trees have been fed to the cattle, and that amount of time has been lost. In many cases no trees of the most desirable kinds have been left to produce seeds. On the contrary, the trees which are left in abundance are the least valuable. It is as though a farmer should destroy his seed corn, but allow the weeds to ripen seeds by the million. It is the survival of the unfittest. Beech, which is of little value here, is left in greatest abundance. It is a fine and useful tree in the original forest, the trunk tall and straight, but on the borders and in openings made by cutting out other trees, the smaller Beeches send out large laterals near the ground, and are practically worthless. Many of the Sweet Gums (*Liquidambar styraciflua*) have escaped destruction because of the difficulty of hauling them out of the wet places where they thrive, and they are now really valuable trees. The Birches which are found near them in the wet grounds are small trees, and are seldom used. Many fine Sycamores have also been left because they are not easily accessible. They stand on the bank of the river, leaning toward it, or are hemmed in by impassable sloughs.

The Sugar-Maple is an exception to the statement that the unfittest of our trees have survived. It heads the list of trees that pay yearly dividends while they live, and are valuable for lumber, fire-wood, etc., when they are cut down. A farmer who has a sugar-orchard and a dairy compares his Maple-trees to his cows, which are made into beef when they are no longer profitable for butter. The Hickory, Chestnut, Walnut and Butternut may yield delicious fruit year after year for a century or more, and make lumber in the end, but it is a common remark here that no other crop the farmer can produce pays him better than the sugar crop. How unfortunate, then, that cattle have been allowed to destroy the young Maples in nearly every sugar orchard in the country. The Maples that have yielded sugar from twenty to eighty years or more are growing old and dying out, and there is no rising generation to succeed them. They are wonderfully prolific, and the young ones thrive better the more other timber is thinned out. Fence out the cattle, and a thicket of young Maples will spring up to take the place of the old trees that are passing away. Neglect to do this, and it will soon be too late.

One objection which is urged against the exclusion of cattle from the sugar-orchard is that the undergrowth which springs up blocks the way, and hinders the gathering of sap and the getting out of timber and fire-wood. But it costs but a trifle to mow the usual roadways and passages close to the ground once or twice a year. But if it is too great a hardship to exclude the cattle permanently, keep them out at least until the tops of the young Maples and other desirable trees have grown above the reach of their teeth. Sometimes about two-thirds of the young growth is Ironwood. I should cut out the parent Ironwoods and other undesirable trees to prevent their seeding the ground. It is sometimes said the profit to be derived from the protection of a new growth is so far in the future that even our children will not live long enough to receive any benefit from the results. This is a mistake. It does not take several hundred years, as many suppose, for trees to grow and become useful. I know of whole orchards of Maples that could have been cut down with a pocket-knife when I first saw them, and which are now magnificent trees, the yield of sugar to the tree being above the average.

Forest-fires are infrequent with us. The wood-lots being small, from a quarter to a sixth, probably, of the whole area,

and being surrounded by cultivated fields so much larger, no fire can spread far. When fire does any considerable damage it is the result of carelessness on the part of wood-cutters, who leave the brush strewn over the ground. If the brush is properly piled, and every few rods a space is cleared of dead logs and branches, a few men can prevent any fire from spreading. I lately visited a piece of woods a few acres in extent that I saw burned over early in the summer. It was in one of the few blocks of forest in this region from which cattle have been excluded for a number of years. The young Hickories, which have deep tap-roots, are sprouting up again vigorously, but the fire seems to have killed all the little Maples.

With the destruction of so large a proportion of our forests have come great changes in our streams. Formerly the water of the snow and rainfall of winter and spring was held back by the shade, and by the accumulation of porous mulch and swamp deposits in the forest, and it flowed more steadily into the streams during the whole summer. Now the water from heavy rains dashes rapidly from the land into the streams, carrying away immense quantities of soil from the plowed fields, filling the rivers with mud, and causing disastrous floods in the Ohio and its tributaries. The undergrowth of the forests being destroyed by cattle, the wind sweeps freely under the trees, the leaves containing the fertility of the forest-soil are blown into the water-courses and lost in the floods. Thus the soil of the whole region, in field and forest, is growing poorer from this cause as well as others. The primitive store of forest-carbon which made our virgin soils so black and mellow, which by its slow oxidation has produced the acid solvents to digest rocky silicates and liberate their imprisoned plant-food, and which by the same slow combustion has caused the formation of those compounds of nitrogen which are the vitality of soils—this store of forest-carbon is fading out, leaving the soils hard and poor. On the other hand, the streams fall so low in summer that it seems probable that some of them would go dry entirely during the hot months if all our forests were destroyed. It seems, too, that the destruction of our forests tends to produce extremes of climate, colder in winter, and drier and hotter in summer, with less rainfall when it is most needed. The water held back by forests in summer tends to cool the air and promote rainfall.

The past history and present condition of our forests are full of admonitions. If population continues to increase, and the present treatment of our forests is continued, some of the children now born may live to see the people burning brush, weeds and corn-stalks for fuel, as is done in some older countries. Our improvident methods tend to destroy all our natural resources and reduce the coming generations of our country to a condition of poverty and want like that of Italy. Our stores of coal are being wasted even more rapidly than our timber. In the Hocking Valley, I am told, only about one-third of the coal in some mines is brought to the surface; the other two-thirds, being of a poorer quality, is hopelessly wasted in the mire of the worked-out mine. When we visit our lumber-yards and pay a good deal of money for a little Michigan lumber for necessary repairs, memory goes back to the time when we had abundance of White-wood and Cucumber, even for barn construction, and the imagination goes forward to the future, and we wonder where the luxury of a little lumber for any purpose will come from when the Michigan Pines are gone, as lumbermen from that state tell us they will be in a few decades at the present rate of consumption; for the hope of future Pines is blotted out by the great fires that follow the axe in that region. How much better for the generations that are to follow us if a few White-woods could be growing here now for their use. How much better for them to import more of some lighter product of the soil from other states, and pay less freight on the lumber which must then come from distant lands. The present tariff on lumber does not seem to promote the production of trees, but rather their destruction.

What can be done to initiate a more rational treatment of our forests? First of all, the people must be enlightened in forestry matters. The majority of land-owners see nothing wrong in present methods. Many do not even comprehend the reproduction of forests in accordance with the laws of vegetable growth, but suppose that young trees spring up without seeds, by "spontaneous generation" or some magical process. Few owners feel that they have any personal interest in the future of their forests. Most of them regard such considerations as impractical and visionary. This state of mind must be corrected by an enlightened public sentiment. I well remember when the market value of land in this region was not diminished by cutting off the valuable timber on it. It was a common remark—"I can sell off the timber for more

than the land will bring, and can then sell the land for as much as though I had left the timber standing." This abnormal state of the land-market was the result of deplorable ignorance on the part of the general public and of those who purchased land. To-day the man who pastures his forest-plot and cuts off the hope of a forest for future needs, can sell his farm for just as much, other things being equal, as can the more civilized and provident man whose forest-plot is covered with a young growth of valuable trees. Enlighten the public regarding forestry subjects and the market will recognize the value of the growing crop of young timber, as it now does that of the crop which is full grown and ready for use. Under the influence of an intelligent public sentiment a man will care for the future of his forest, and its consequent increase in market value, as thoughtfully as he now does for the market value of his horse. Other corrective influences might be considered, but one must serve as the concluding word. We need most of all an enlightened public conscience which shall recognize a moral and ethical side to business matters, a sentiment which shall give honor to those who are willing to bestow some thought and work for the benefit of posterity, for the happiness of their children's children, as well as to those more selfish, whose greatest care is to get money now.

Recent Publications.

History of Botany (1530-1860). By Julius von Sachs. Authorized translation by Henry E. F. Garnsey, revised by Isaac Bayley Balfour. (Oxford: Clarendon Press, 1890; 8vo, pp. xii., 568.)

The present translation of Professor Sachs' work, which appeared in Germany in 1875, is intended to supply the want, long felt by English-speaking students, of a history of botany in English, for, strange to say, there is no English work on the subject in existence. Unlike the older histories of Kurt Sprengel (1818) and Ernst Meyer (1857), which abounded in technical facts, so that, in reality, they were encyclopædias quite as much as histories, the present work attempts to give a bird's-eye view of the science from its origin until the date of the appearance of Darwin's "Origin of Species," which marked the beginning of a new era in botany. The book is divided into three parts, treating respectively of the History of Morphology and Classification, the History of Vegetable Anatomy and the History of Vegetable Physiology. The first and third parts cover the ground since 1530; but vegetable anatomy, a study which requires the use of good microscopes, is of more recent origin, and, according to Sachs, does not go back farther than 1671.

Botany, as a science, did not exist among the ancients, and what passes for botany in the writings of Aristotle, Theophrastus and Pliny is merely a crude description of plants almost buried in a mass of philosophical speculation, and, until comparatively recent times, the history of botany is mainly an account of the struggles of learned men to free themselves from Aristotelian preconceptions and to substitute a knowledge founded on exact observation for vague hypotheses. The first object in science is to obtain a large number of facts; but the ultimate aim, as is strongly and repeatedly urged by Sachs, should be to discover the general laws to be obtained by a comparative study of facts. Throughout the whole of the present work we find brought into strong contrast the observers and accumulators of facts, on the one hand, and the more philosophical reasoners, on the other. In his admiration of the latter class it may, perhaps, be questioned whether Sachs has not, unintentionally, somewhat underrated the former. He apparently regards it a defect in Mohl that, although an observer of the first class, he was disinclined to draw general conclusions from his observations. But a comparison of Mohl with Schleiden, who had no hesitation in laying down general laws from imperfectly understood facts, leaves no doubt as to the superiority of Mohl, a superiority due, as one may think, in some measure, to his disinclination to theorize.

Of the three parts of Sachs' History, that relating to morphology and classification is the least satisfactory, and the one least interesting to the general reader. Contrary to the general impression, Sachs believes that the conception of genera preceded that of species in the writings of earlier botanists, and what he says on this subject certainly has a great deal of force. The place of Linnæus in botany has been much discussed. Just now it is the fashion to say he was much overrated. He was not an experimenter as was Camerarius, who was the first to prove the sexuality of plants, but Linnæus did not claim to have discovered sexuality. But, as Sachs admits,

Linnæus was acute enough to be able to sift the truth from error in the work of his predecessors, and, if he was not entirely free from Aristotelian methods in his reasoning, he was able, as was no other before him, to present a clear and comprehensive system which prepared the way for subsequent classifications. It is hardly necessary to hint that he was not the author of the binomial system, for all attempts to prove the contrary have only resulted in showing that he was certainly the first to advocate and practice such a system. On the whole, recent endeavors to belittle Linnæus have served only to make his superiority the more evident.

The chapters on anatomy and physiology will be found to be much more interesting than those on classification, and, whether one agrees with the author in his estimate of individual botanists or not, they form a most admirable summary of the subjects. The style of the original was clear and forcible and its characters have been well preserved in the excellent translation, which follows the original German, except in a few places where, as the author states in the preface to the translation, changes "could be effected by simply drawing a pen through a few lines."

On closing the book the reader who has followed the course of botany since 1860 cannot fail to remark how great has been the change in the science since that date. The "Origin of Species" certainly has brought about a new epoch in botany. Looking back to 1860 it seems to be but a short time, but there has been a revolution in scientific ideas. One would be glad to have from Sachs, who has himself contributed so much to recent advance in botany, a summary of progress since 1860, and the desire is only intensified as one reads in the author's preface the following lines: "I would desire that whoever reads what I have written on Charles Darwin in the present work should consider that it contains a large infusion of youthful enthusiasm still remaining from the year 1859, when the 'Origin of Species' delivered us from the unlucky dogma of constancy. Darwin's later writings have not inspired me with the like feeling." One would be glad to know exactly which works of Darwin are here meant and why they have failed to inspire the like feeling. Are we to attribute the change of view to the conservatism which naturally increases with age, or are we to conclude that a maturer reflection has convinced Sachs that science has advanced too fast and too far in the direction of Darwinism, and that the pendulum of progress is to oscillate in another direction hereafter?

Correspondence.

Orchids in New Brunswick, New Jersey.

To the Editor of GARDEN AND FOREST:

Sir.—In the gardens of Charles J. Carpender, Esq., of New Brunswick, New Jersey, I recently found a rich display of flowers scattered through the three houses devoted to the culture of Orchids. There were also fine groups of Nepenthes, Anthuriums, Ferns, etc., growing luxuriantly. Among the Anthuriums was a grand form of *A. Andreanum*, bearing flowers of enormous size, some of the largest measuring nine inches in diameter. The Nepenthes, too, were furnished with pitchers of fine form and color, among them being good examples of *N. Amesiana*, *N. Hookeriana*, *N. Dominiana*, etc. Among the Orchids, *Lalia purpurata* made the most prominent display, with its large and bold blossoms, and several excellent varieties were seen, one especially being very distinct, with broad, flat sepals and petals, and a lip of a very rich purple color. The plant bore six spikes, carrying some thirty flowers. Near the roof of the house a number of the beautiful rose-colored *L. majalis* were seen, and, judging from the enormous flowers they bore, this position suited them exactly. One plant had produced two spikes, one with three, the other with two flowers. They were attached to wooden blocks, and when growth is completed they are removed to a cool and dry atmosphere to enable the bulbs to mature thoroughly, and this Mr. Carpender considers the main cause of his success. Among the Cattleyas several fine examples of *C. Skinnerii* were well flowered; also *C. Gaskelliana*, and the old but still popular *C. Mossia*. Many others promise a fine show at a later period, among them being several plants of *C. Dowiana*, well sheathed *C. chrysotoxa* and *C. gigas*, all grown in baskets, and in vigorous condition. Several interesting Cypripediums were also seen in flower, chief among them being two large examples of *C. caudatum*, with its curious tail-like petals. The pretty *C. Lowii* had furnished a strong spike, and a group of *C. Lawrenceanum* were all in fine condition, their dorsal sepals being very broad and large, and in one va-

riety the whole flower was suffused with purple. *C. Domenii*, *C. Sedeni*, *C. callosum*, *C. Warnerii*, and others, added to the display; a plant of *Uropedium Lindenii* was in full bloom, its quaint flowers reminding one of a pouchless Cypripedium, and by its side was *Eulophia pulcherrima*, and, though not a very showy variety, its blossoms were well marked. Some excellent Dendrobiums were hanging at the warmest corner of this house; among them several examples of the white flowering *D. Dearei*, bearing clusters of its butterfly-like blossoms. *D. Bensoniæ* also was well flowered, its white sepals and petals, together with its deep maroon centre, making it very attractive. One plant of *D. Pierardii* had produced scores of its pink and primrose-yellow flowers. *Vanda teres* grew very well in this house, and had produced several fine blooms. They were placed in baskets with moss and a good drainage. *Chysis bractescens* was represented by a plant of large size, bearing a number of its bold, wax-like flowers. Some remarkable specimens of *Peristeria elata* (the Holy Ghost Plant) were in robust health, and dozens of spikes were rapidly pushing for flowers. Some stout spikes of *Odontoglossum vexillarium* were rapidly developing, and will later yield a fine display. In the Odontoglossum house there were a number of the beautiful *O. crispum Alexandra*, carrying well flowered spikes, among them several of the true broad petaled type. Here also *O. Cervantesii* was flowering profusely, one plant carrying some two dozen flowers. Quantities of *O. Rossii* were also well bloomed, together with *O. Pescatorei*, *O. cordatum*, *O. roseum* and many more.

The Rest of Plants.

To the Editor of GARDEN AND FOREST:

Sir.—Referring to your suggestion that I should write something on this subject, I may add to what has already been said (see GARDEN AND FOREST for April 16th, page 195), that practically, as I suppose, all plants have, or are the better for, a rest; but it is hardly conceivable that there is any absolute cessation of activity short of death. In the so-called dormant or resting period chemical and molecular changes advantageous to the plant are, no doubt, going on. When there is a sharp change in the conditions from a fall in temperature or from lack of an adequate supply of water, then the "rest" is more pronounced than is the case where the conditions are more uniform. In equatorial countries, where the climate is nearly uniform throughout the whole year, growth is also continuous. So in the cultivation of evergreen Orchids, or of bulbs which bear their leaves the whole year, it is evident that the "rest" is different in degree, at least, from that which obtains in cases where the leaves die off, and the treatment must be correspondingly different. Generally speaking, plants may be "rested" by submitting them to a lower temperature and by withholding water. In some cases, as with bulbs, tubers of Dahlias, etc., lifting the bulbs and storing them in a dry place to which frost has no access insures as perfect rest as can be had. But that Nature will have her way is shown by the circumstance, that bulbs and tubers (for example, of Potatoes) will sprout in dark cellars in spite of our care.

So far, then, as relates to "directions for resting plants which may be of service to an amateur window-gardener," I should say that he should make himself acquainted with general principles, and, with that knowledge as a basis, with a little zeal and more patience, he will soon learn to apply them successfully, and in so doing get to learn the habits and the natural rest-season of each plant or species. The more nearly we can cultivate our plants as "annuals" the more successful we are likely to be; this, of course, involves a rhythmical alternation of activity and dormancy.

As to books which treat of this subject on this side of the Atlantic, we still turn to Lindley's "Theory of Horticulture" and Thompson's "Gardener's Assistant"; but more recent information is contained in the Introduction to the "Epitome of Gardening" (Black) and in "Plant Life" (Bradbury & Co.).

London.

Maxwell T. Masters.

Notes.

As it is now autumn in the southern hemisphere apples are coming to the English market from Tasmania. The fruit is said to be of excellent quality, and it arrives in first-rate condition.

The death is announced of Sir John Henry Lefroy, a distinguished officer of the English army, Governor of Bermuda from 1872 to 1877, of which he published an account including a catalogue of Bermuda plants with notes on their distribution.

and economic properties and uses. This, under the title of "The Botany of Bermuda," was republished in the *Bulletin of the National Museum of the United States*, No. 25.

Mr. F. H. Vaslett records the fact in *Zoe* that the European Daisy (*Bellis perennis*) has succeeded in establishing itself in one of the glens of Mount Tamalpais, near San Francisco.

Part XVI. of the "Flora of British India," by Sir J. D. Hooker, completing the fifth volume of that great work, has appeared. The Orchids are finished in it.

Several well-rooted young Fig-trees lately arrived at Auburn, California, from Smyrna. The trees, together with some cuttings, were in excellent condition. They came from the Aidin district and are said to be the true Smyrna variety.

A few of the fine dates which come from Africa attached to the stalk on which they grew are still coming in, and among the rarer fruits from the West Indies are a few Star Apples (*Chrysophyllum Cainito*), the red and yellow Mammee Apples (*Mamea Americana*) and Sapodilla Plums (*Sapota Achras*).

Mr. Sereno Watson, the Curator of the Herbarium of Harvard University, and Dr. E. von Regel, Director of the Imperial Botanic Garden at St. Petersburg, were elected foreign members of the Linnean Society at the meeting held on the first day of May. The number of foreign members admitted to the Society is small, and the honor of foreign membership is considered one of the chief marks of consideration a foreigner can receive at the hands of British naturalists.

The flowers of *Magnolia Fraseri*, which have been open for a week near Philadelphia, are of a light canary color, and with almost the same exquisite fragrance which characterizes those of the Swamp Magnolia. A large specimen of this species still stands in Bartram's Garden, and Mr. Joseph Meehan writes of two others in Germantown, one of which is thirty-five feet high, and, although it flowers profusely every year, it never perfects seeds. We have also received from the Meehan Nurseries a flowering branch of a variety of *Viburnum plicatum*, known as Rotundifolium. It seems quite distinct, with reddish twigs and tinted leaves, and comes into flower several days earlier than the typical plant.

Rhododendron Vaseyi, of which a figure and description were published in the first volume of GARDEN AND FOREST, more than sustains its promise as a garden plant. It has flowered profusely this year in the Arnold Arboretum, where it proves perfectly hardy, and where, with the exception of the Rhodora, it is several days earlier than other plants of its class. The bright pink color of the flowers, not very different, although rather paler than that of a good La France Rose, is quite unlike that of any other Azalea. It now seems safe to say that this plant, long overlooked in the valleys of the Blue Ridge, will prove a garden plant of the first class. It may be expected, too, to exert considerable influence in the production of a new early flowered race of Azaleas.

Mr. C. L. Anderson describes in the second number of *Zoe*, the new California monthly, a curious monœcious Willow which he finds in his garden at Santa Cruz, and which, moreover, is not uncommon among the trees of that part of California. He first considered it a form of *Salix lasiandra*, but having found several trees with male and female flowers on the same ament, he reached the conclusion that it is a hybrid between *S. Babylonica* and *S. lasiandra*, the former having been introduced early into California, where there are now many fine, large specimens. The supposed hybrid trees have sometimes a weeping habit, so that they can hardly be distinguished from the genuine Weeping Willow, and in others they closely resemble in habit the California species.

The large flowered form of the Scarlet Hawthorn (*Crataegus coccinea*, var. *mollis*) was a conspicuous feature in the middle of May on the wooded banks of Westchester County. This is the earliest of our native Thorns to flower and this year the plants have been so covered with flowers as to light up the landscape in every direction. This Thorn is not only the earliest of our species to flower here, but it is the largest of the Thorns of the northern states. Trees twenty to thirty feet high are not rare. The flowers are large and handsome. The fruit, which ripens early, is large and brilliantly colored and the ample foliage turns bright before it falls in autumn. The habit of the tree is excellent and it should be cultivated much more frequently than it is. The only drawback to it is in its liability to be attacked by a fungus which sometimes disfigures the foliage and fruit late in the season.

One of the most beautiful and effective plants which have lately flowered in Central Park is the Black Haw (*Viburnum*

brunifolium), a large, tree-like shrub which is one of the native plants of this vicinity, although much more common further south. It was planted long ago, fortunately in large numbers, in the park, where many specimens have now grown to a large size; and this year they were unusually full of their large, flat clusters of white flowers, which, later in the season, will be followed by bright blue-black berries. The Black Haw, as it appears in the park this year, is another example of the great value as ornamental plants of many of our little known native shrubs, among which are to be found the safest and therefore the best material for the decoration of parks and pleasure-grounds in the region where they grow naturally. Our flora contains some of the most beautiful trees and shrubs known to man, but Americans, or those who plant gardens, are only just beginning to realize the fact and to learn that they must depend on the native products of the soil for the best material for their plantations. A desire to imitate what is done in other countries has certainly had some deplorable results in retarding the development of American garden-
ing.

The meeting held in Boston on Saturday last, at the invitation of the Appalachian Mountain Club, to consider the best means of preserving fine scenery and places of historical interest, was attended by persons representing all parts of Massachusetts. Mr. George C. Mann, President of the Club, spoke of the 400 cordial answers to the invitation which had been received, and he mentioned especially the replies of Governor Brackett, Mr. Whittier, Mr. Francis Parkman, Colonel J. W. Higginson and other distinguished citizens. Addresses were made by Mr. Charles Eliot, Mr. J. B. Harrison, Hon. Leverett Saltonstall, Professor Norton and Judge Shurtleff. The chairman, President Sprague, of the State Senate, was authorized to appoint a committee, with power to add to their number and in such ways as may seem advisable to effect the establishment of a Board of Trustees empowered to acquire land and hold for the benefit of the public beautiful or historic spots in any part of the commonwealth. The following persons were appointed on the committee: President Francis A. Walker; Miss Sarah H. Crocker, Miss Marian Talbot and Mr. George Wigglesworth, of Boston; Dr. Henry P. Walcott and Mr. Charles Eliot, of Cambridge; Professor C. S. Sargent, of Brookline; Mr. Henry M. Lovering, of Taunton; Hon. Henry L. Parker, of Worcester; Judge William S. Shurtleff, of Springfield; and Dr. J. F. R. Adams, of Pittsfield. Subscriptions to a working fund may be sent to Mr. George Wigglesworth, 89 State Street, Boston.

The annual meeting of the City Parks Association of Philadelphia was held last week on the spacious grounds of Mr. Justus C. Strawbridge, in Germantown, and a most encouraging occasion it proved, with Colonel McClure in the chair and admirable addresses by Dr. S. Weir Mitchell and Mr. Hampton L. Carson. The purpose of this association, which was organized a few years ago under the name of "The Philadelphia Open Space Association," is to open up small parks and squares in the thickly populated portions of the city, and to secure for public use open spaces on the outskirts of the city's built up area, which otherwise would soon be covered over with buildings. The association under its present name has been organized only two years, but with the active aid of the public-spirited men and women who form its membership the city authorities have located the following small parks: Stenton Park, of about thirteen acres, including the homestead of the Logan family, near Wayne Junction; Weccacoe Square, at the corner of Queen and Cobb Streets, the only spot not built upon in the Third Ward; Bartram's Garden, the ground of the famous botanist of the last century, with its collection of rare trees and shrubs still preserved; Northwood Park, with its picturesque brook and meadow, in the neighborhood of Frankford; Juniata Park, a wooded height overlooking a creek, but immediately adjoining the vast manufactories of the Twenty-fifth Ward; and Riverview Park, giving a view of the Schuylkill from the heights above the Pennsylvania Railroad, near Thirty-second Street. In addition to this public action private beneficence has added to the number of parks by the gift to the Association of the Starr Garden, on St. Mary's Street, by Miss Anna Hallowell; the present to the city of a square of ground, in the southern section, by Mr. Edward C. Knight; and of a tract of about five acres, near the junction of Haines Street with the Chestnut Hill Branch of the Reading Railroad, to be known as Waterside Park, by the heirs of the late Reuben Haines. The public spirit and civic pride of Philadelphia have passed into a proverb, but these qualities have never been more worthily exemplified than in the work of this model organization.

The Lumber Trade Journals.

IN all the older parts of our country where there are no government lands; the various interests which depend upon our forests and woodlands are chiefly in the hands of individual land owners and of lumbermen and it is important therefore that the persons interested in forestry should come into close relations with these two classes. The lumber trade papers and the recent improvements in their character are on this account worthy of special notice. They show marked gains in breadth of view and in seriousness, and the discussion of trade subjects is more direct, definite and business-like. The assumption that only lumbermen can have practical ideas on forestry subjects has been outgrown, and writers for the leading lumber journals recognize the community of interests which is involved in nationality and civilization, and which binds all the people of our country together. The clear perception of the fact that the functions of forests and their relations to the future timber supply of the country, the permanence of the streams and the fertility of the soil are matters in which all intelligent and patriotic Americans should feel interested, is a distinct advance.

The increased earnestness is the greatest gain. This has been brought about naturally by the operation of the laws of business and by the immense development of the interests represented by these papers, and these processes of expansion and improvement are still going on. Not long ago the writing in lumber journals—there was not much of it indeed—seemed intended to be humorous rather than informing, and the selections appeared to have been made by the office boy when in a hurry to get away to a ballgame, as they often had no relation to the objects of the paper, but merely filled up the space. At present the leading lumber papers are usually pretty well filled with interesting matter. Some of them have valuable special contributions descriptive of the timber resources of various regions of our country, which are evidently based on actual observation.

In some instances the old fashion of “bright” writing, which has no relation to facts, is still followed, but the

method of accurate reporting, which is the basis of all real journalism, is gaining ground. One of the western lumber papers had an editorial article on the late annual meeting of the American Forestry Association at Philadelphia, which contained exactly as many errors as items of statement. The misrepresentation in such cases is not what most deserves attention, but the lack of intellectual seriousness, the slight way in which the writer manifestly thinks of his own work and of the important interests with which he deals.

The editor of a lumber trade paper has a chance to make his place highly influential and useful. This department of American journalism has undeveloped opportunities and capabilities which should make it attractive to young men of ability and education in the lumber business. There is no reason why the best writing of the time on forestry subjects should not be done in the offices of these papers, if such young men equip themselves with adequate knowledge and with the power of comprehensive thought. This last is one of the most important requirements for the people interested in forestry, too. They need to be able to “look before and after,” as Shelley says, to understand relations and tendencies, and to estimate rightly the effect of forces which operate slowly. Our country needs more men who can think of interests beyond the limits of their own farm, town or state. Some men in New England, for example, think the discussion and agitation of forestry subjects unnecessary, because in their neighborhood there is more woodland than there was thirty years ago. We call a worn out field woodland, though it may have but half a dozen specimens of *Pinus rigida* to the acre, and these worried and crippled by cattle past all possibility of useful growth; and though the area of woodland may have increased, there is, in many instances, far less of valuable timber than formerly. A jaunty and superficial optimism is often comfortable for thoughtless people, but no man can treat our national forest-interests adequately who does not understand the possibilities of tragedy which are involved in our methods of mismanagement.

What do the intelligent and public spirited men who are interested in forestry subjects desire? What are their wishes and aims? That the forests and woodlands of the country shall be managed intelligently, so that the greatest benefit, service and profit for all concerned can be obtained from them. What do sensible and practical lumbermen and owners of timber lands desire? Precisely the same things, of course. We are all interested in forestry, as we are in agriculture, and whatever leads to wiser knowledge and better methods advances the general welfare. The lumber people and the forestry people are alike interested in having timber cut off with foresight and calculation, and in having the land so cared for and protected that the timber will grow again, and that it will be perpetually reproduced on all land which is fit for no other crop. What is the good or sense of wanton waste and destruction, however limitless our supply of timber may be supposed to be? Not many years ago a citizen was remonstrating with an army officer when he and his men had killed over thirty buffaloes one afternoon, when only their tongues, and not all of them, could be used. But the officer replied that if the whole army of the United States were constantly employed in killing buffaloes no impression could be made upon their numbers. He is still living, but he will never dine on buffaloes’ tongues again.

Not long ago it was pointed out to a farmer in southwestern Iowa that if the Black Walnut which he had been cutting for firewood for thirty years had been allowed to stand it would now have been worth more than the entire farm would sell for without it. He was surprised, but, after a few moments, said he did not doubt it. “But,” he added, “it is too much trouble to think of anything so far ahead.” Perhaps we cannot reasonably expect the mass and average of our fellow-citizens to learn to act with habitual recognition of laws and forces which operate so slowly

as those which manifest themselves in the relations of forests to the welfare of men and nations, but unless the teachers and leaders of the people are capable of such foresight our proper national destiny is imperiled. The nation which cannot take care of its forests, its streams or its soil is likely to be found wanting in other things when new conditions arise requiring wisdom, forethought and self-control.

We all need to learn. It is not safe to assume that any class of people knows all there is to be known on any subject. When we differ let us express our opinions plainly and directly, and stand up for them man-fashion, and expect other men to do the same. It is good American style to say what we mean and mean what we say. No important subject of our time has yet had adequate discussion in this country. It is of the first importance that forestry subjects should come to be regarded as matters of general public interest and concern; that they shall not be fenced off into a narrow arena for petty contentions between specialists, the forestry people on the one side and lumbermen on the other, while the country remains generally indifferent and absorbed in other affairs. These subjects are so large and vital, and have such relations to our national welfare, that it is reasonable that intelligent and practical men should inform themselves regarding them. They can do this only by acquaintance with the literature of these subjects, and with their systematic presentation and continuous discussion in journals which treat such topics intelligently and earnestly. All thoughtful men will, therefore, wish for the lumber trade journals the greatest possible success.

OUR London correspondent describes in another column an interesting meeting of the Royal Horticultural Society, held on the 13th of May, at which a discussion upon hardy trees and shrubs with showy flowers was the principal feature, considerable collections of the flowers of such plants being shown by the authorities of the Royal Gardens at Kew and by some of the nurserymen who make a specialty of cultivating them. This exhibition and the discussion which it provoked are indications, perhaps, that the English, who still set the fashion to the world in gardening, are at last beginning to realize that they have unduly neglected of late years deciduous trees and shrubs in favor of evergreens, which, as our correspondent points out, have been too much planted in England during the last thirty years. They have their place, and have greatly increased the material available for the use of the modern gardener. It is equally true, however, that modern English gardens have been made monotonous and uninteresting by the excessive use of such plants, which, even in England, do not thrive everywhere, and which in cities and their suburbs seem always out of place because they are never really healthy when brought within the influence of city smoke and dirt. We in America can well rejoice at this change of English feeling, or, to speak more accurately, this return to the ideas of the early part of the century, when deciduous trees and shrubs with handsome flowers were held to be the chief ornament of the garden. We have followed the fashion set in England here and tried to cultivate conifers and broad-leaved evergreens, generally with the most unsatisfactory results. The climate of eastern America is not favorable to plants of this nature; but if deciduous trees and shrubs are to become fashionable again, we have all the natural conditions in our favor, and if we cannot show the world the effects such plants are capable of producing, it will be because our gardeners lack the intelligence to strike out for themselves and make the most of their advantages.

American gardening, as has been said before more than once in these columns, if it ever ceases to follow foreign fashions and attains to a national school of its own, will owe its excellence to a more general use of deciduous plants than now prevails, and to the development of new and better forms of such plants.

It is only a visit to Central Park on a pleasant Saturday afternoon in May, when the lawns are covered with children, that can give the real idea of its immense value to this city. Many of these children dwell in crowded tenement-houses, and the full enjoyment of a breath of fresh air amid rural surroundings must seem to them like a foretaste of heaven. It seems incredible that any one with any interest in New York and in its people, with the memory of such a sight in his mind, can for a moment be willing to see any part of the park alienated from the purposes which primarily make it useful, and devoted to any other use. Central Park is truly a marvelous creation, when it is considered what it was made from, and that it is in the heart of one of the large cities of the world. Its supreme merit lies in the fact that it reproduces Nature as no other great-city park in the world does, with the single exception of Prospect Park, in Brooklyn. As compared with the parks of London, Paris, Berlin or Vienna, Central Park is pure country, where the city-dweller can forget bricks and mortar and revel in the delights of trees and grass, of moss-covered rocks, and meadows dotted with wild flowers. There are prospects in Central Park, like some of those from the foot of the terrace looking across the lake, which are as far removed from all idea of city surroundings and city life as if they looked out upon the banks of some lake a hundred miles away in a remote and wild part of the country; and these views represent all of the country that thousands of children born in this city ever know. Surely every effort to deprive our people of any of the natural beauties of Central Park must be thwarted, whatever effort it may cost the intelligent men and women who have at heart the best interests of the city.

The park is already too small for the demands made on it by the public. In a few years it will be so crowded on holidays that its usefulness will be seriously interfered with. No part of it, therefore, should be given up for any purpose whatever which in any way will interfere with its real mission, which is to bring to the people of this city a little of the country and its civilizing and health-giving influences.

A Stone Bridge in Wales.

AS an interesting contrast to the stone bridge at Topsfield, Massachusetts, which we illustrated a short time ago, we give on page 275 a picture of a similar bridge in Wales. The picture speaks for itself with regard to the beauty that such bridges have, no matter what the character of their surroundings may be. In the former instance we saw a quiet, pretty stretch of river, the banks overhung by low trees and shrubs, and no buildings in sight. Here the bridge forms a feature in a village street, yet it is just as appropriate and just as charming. Of course were these simple but solid stone houses replaced by wooden ones of the usual American type there would be less harmony and less dignity in the picture. But, at least in our older villages, the wooden houses stand beneath great Elms and Maples, which give beauty of a different kind; and in a street thus composed a stone bridge would be an equally fortunate detail. The thick growth of Ivy that covers the sides of the Welsh structure could not everywhere be reproduced in our colder, drier climate; but we have enough vines of our own to clothe bridge or river wall most beautifully, during the summer season at least. And even in their winter nakedness they would still be attractive, while the cheap bridge of wood or iron is hideous when naked, and only tolerable even when draped with green.

The Trees of Persia.

NO country, within the same limits, presents such vivid contrasts of scenery and vegetation as Persia. There are wide districts which have all the characteristics of the Desert of Sahara, while only a day's ride from there one climbs stupendous mountain ranges or plunges into the depths of forests where the sun is hardly seen and the music of the cataract reverberates through a primeval solitude. The centre and south of Persia is a vast arid table-land from 3,000 to 4,000 feet above the sea. Here and there it is intersected by mountain chains many thousand feet high, covered with perpetual snow. The melting of this snow furnishes the water which,

by laborious irrigation, causes vegetation to prosper around the cities or in artificial oases. Naturally, there are no forests on this plateau, and the large province of Khorassan, some 60,000 square miles in extent, is chiefly a salt-sand desert, having water only at long intervals. This district is supposed to have been the bed of a sea like the Caspian, which gradually evaporated, as the Caspian is now doing.

On this plateau Poplars, Mulberries, Walnut-trees and almost every variety of fruit-trees can be made to flourish by irrigation; but evergreens, like the Pine, do not seem to take kindly to the soil or the climate. The Peach is indigenous to this region; the Fig grows well, although inferior to that of Asia Minor. The Quince of Ispahan is famous; its flavor and fragrance are unsurpassed. The Pomegranate is also a favorite tree of the Persian plateau. But all these trees are there dependent on irrigation. Stop that, and the spirit of the desert, in a very short time, resumes its sway.

But the most remarkable vegetable phenomenon of the Persian plateau is the Chevar or Plane-tree, called with us the Buttonwood-tree or Sycamore. Every Persian garden has some of these trees. They are planted in rows near together and trimmed high up so as to produce a lofty shaft. A double purpose is served by this process—shaded avenues are obtained and timbers for roofing the dwellings of adobe. The scarcity of timber in Persia renders this a most important object. Plane-trees and Poplars are one of the most valuable sources of revenue to a Persian proprietor. The avenue of these trees extending from Teheran to the villages of the Shimrân, where the wealthy resort in the warm season, a distance of some eight miles, form an appanage of the chief wife of the Shah, who makes quite a revenue from the annual product of this timber. But the Plane-tree in this form is the result of cultivation. It is in its natural state, as it grows without the intervention of man, that it chiefly concerns us here. The Sycamore is reputed by tradition to have been the tree cursed by the Saviour for its barrenness. In the remotest times legends clustered about it, especially among the Persians. Alexander the Great, on his march to Hyrcania, is said to have come across a pair of Plane-trees in the north of Persia—one male, the other female—which, in a mysterious conversation, foretold his destiny and his doom. Marco Polo has much to say of this tree in speaking of Persia; and it is very remarkable that he generally writes of that country as the *Arbre See* and the *Arbre Sol*, thereby indicating what a prominent feature of the Persian landscape and vegetation the Plane-tree was in those days, in so much that it gave a name to the country.

The Platanus is indeed a most eccentric and extraordinary tree, as one sees it in Persia. It enjoys water courses and shady valleys, and it grows in the desert far from water with equal satisfaction apparently and with equal grandeur. It is by far the noblest tree of central and western Asia in its form and dimensions. The Plane-tree under which Godfrey of Bouillon encamped by the Bosphorus is still standing, a most venerable and gigantic patriarch. Not many years ago a similar tree was standing in Asia Minor which was reputed to be the tree which Xerxes decorated on his way to Greece.

The market-place in the Persian villages, where the streams rush down from the mountains, are always shaded by one or more vast Chevars, under which the peasant rests at noon-day, the cobbler plies his awl, the itinerant musician or physician soothes the rustic mind or body, and the children and the dogs romp and sleep in idle groups. The mosque courtyards in the cities are ever canopied by the spreading boughs of the Plane-tree, and one almost feels that this is indeed a tree which seeks and thrives especially in the society of man, and that abundant water is one of the essentials of its development.

But go forth from the habitations of man, and far from the springs of water, where the soil is yellow sand or pumice-stone, ejected ages ago from the vast crater of Demavend, where there is no herbage, or, at most, only the cynical Thistle; where even birds are few, and these chiefly the eagle and the vulture soaring far up in the blue dome that rains heat over the wastes that quiver with mirage, and which is swept over by whirling columns of dust, and you find the Chevar flourishing there.

I remember a most noble old Plane-tree at Gelandevék, standing by a tank where the Shah's pavilion is pitched when he hunts in that district. Fruit-trees and Melon-fields and rivulets, and a village hidden in foliage, were all about us, and the old tree, still green in its old age, was evidently in congenial company. But from the door of my tent I could look on the yellow and arid side of a great hill, on which the sun pitilessly rained heat. Near the top of the slope stood a large and solitary Plane-tree, the only green thing on the hill. Its

leaves were as abundant and fresh as those of its rival, whose roots rested among the "rivers of waters."

Turning from the central plateau to the south we find the chief feature in the arboreal vegetation of Persia to be the Date Palm, which grows in the neighborhood of the Persian Gulf in such abundance that dates form one of the most important articles of export from the country. On the other hand, in the south-west, in the region bordering on Turkey, extensive forests of dwarf Oak are found, the only examples of the Oak in Persia.

If we turn north again from the central waste lands of Persia we find ourselves confronted by the tremendous ranges of the Elborz, practically a continuation of the Hindoo Kush, extending from Turkistan to Armenia. In Persia it has an average elevation of 9,000 feet, rising to 13,000 feet between Teheran and the Caspian, while the peak of Demavend, forty miles from the capital, is no less than 21,000 feet high, the loftiest mountain between the Himalayas and the Andes. South of the Elborz range stretches the great arid table-land. But when one reaches the top of the ridge he enters with great suddenness, and without warning, upon an altogether different scene. The north side of the mountains faces the Caspian Sea, and condenses the moisture deposited by the clouds driven by the breezes of an inland sea 800 miles long. Here one finds "a land of streams." Everywhere cascades leap down the mountain sides. The roads are often by the side of deep and turbid rivers or carried over them by stone bridges of the most massive character. A piercing wind rushes through the gorges, so violent at some points as to blow men, and even mules, into the rivers. What is yet more remarkable, almost immediately after beginning the northern descent, the traveler enters the gloom of the densest forests in the world. The sun umbrella is laid aside, and whereas the roads were thick with fine white dust, they are now often muddy and traversed by chattering brooks.

The forests, league after league, are Walnut, and here and there Chestnut. The vastness and density of these Walnut forests is extraordinary. They reach almost from the ridge to the sea, a distance of seventy or eighty miles, and east and west over 200 miles, along the rich alluvial strip which borders the Caspian.

In the heart of these forests the mouldering ruins of old castles and towns are still to be seen of which the very name is forgotten, and the tiger, the panther, the wild boar and the wolf roam through the underwood unmolested. Curious wandering tribes also dwell there, doubtless descendants of the legendary White Dios encountered and conquered by Rustem in the glimmering dawn of history.

The glades in these forests are of magical beauty; one may easily imagine himself to be in the realms of the Fairy Queen when at noonday he comes to one of these delicious openings and lunches on a rich green sward, where the air is musical with streams and an abattis of huge massy fallen trunks seems to protect one from the dark ranks of the surrounding forests. One of the most singular features of these forests is the frequent appearance of the Pomegranate growing wild. Its bright green, glossy leaf contrasts vividly with the darker foliage around it, while the exquisite orange-scarlet of the blossoms shines in the emerald gloom like sparks of flame. At intervals, grandly picturesque forests of Olive are seen, chiefly on the river banks; the Elm and the Box also grow there in considerable abundance, and the Poplar is common. But the chief feature of the great forests of northern Persia is, after all, the Walnut. Deciduous trees alone compose that wilderness of woods. On the plain near the Caspian, however, Cypress are sometimes seen, chiefly near the towns, evidently the result of cultivation. It is worth remarking that the northern side of the Elborz reeks with malaria, and dangerous fever lurks in the jungle along the Caspian, while the arid central plateau of Persia is one of the healthiest regions on the globe.

New York.

The Water Supply of Southern California.

CALIFORNIANS are now discussing the forests, swamp-lands and possible reservoirs of the southern Sierras. A very interesting interview was recently held with Mr. S. C. Lillis, of Kern County, the manager of the famous Laguna de Taché ranch. He holds that the proper irrigation system for the San Joaquin Valley is based upon two things—the preservation of the forests and the utilization of the natural reservoir sites. He says that many sheep men have been permitted to obtain rights to the natural pastures of the high Sierras under an incorrect interpretation of the Swamp-land Act. These tracts are situated above the five-thousand-foot level, and are unfit

for agriculture. They are now cut and pastured so closely as to destroy many springs and streams. All the lands above five thousand feet of altitude should be kept for timber and mining, withdrawn from sale and protected.

Mr. Lillis says that for six years he has traveled over the mountains of three counties, a territory as large as Massachusetts, and has seldom been able to find trees of less than twenty years' growth. This shows that the sheep have destroyed all the young timber, and that it has not been permitted to grow. He found that in the high Kern districts, from 8,000 to 12,000 feet above the sea, one-third of the standing timber was dead. Last July and August he was never out of sight of eight or ten forest-fires, and sometimes counted more than twenty. He continues:

"I have asked sheep men for the reasons for so many fires, and they have answered that they did not want their sheep obstructed in their movements by timber and brush, and that they proposed to burn it off. The needles or leaves of the Pine-trees on the Kern and Kings Rivers are removed from the roots of the trees by the sheep, and they are exposed to the frosts of winter and the heat of summer. The frequency of the fires destroys the outer bark, and finally the tree dies. Then the fires catch in the resin of other trees and burn them, leaving the mountains as bare as a desert."

The old settlers in the Sierra region say that an enormous amount of water can be easily and cheaply impounded there. The present system is to construct expensive dams in the cañons near the valley. The proper places for reservoirs are on the high levels in chains of small lakes, and "flats" where the outlet can be raised at a slight expense. There are said to be hundreds of places at the heads of the Sierra rivers that are adapted for water storage. About these natural and artificial lakes the native timber should be allowed to grow, and the sheep pasturage and annual burning of the forest should be prevented. This is the most simple, effective and least costly system that has been proposed, and all the old mountaineers favor it.

New or Little Known Plants.

Phoenix Roebelenii.*

THIS new and distinctly marked species of *Phoenix* was introduced into England about a year ago by M. Roebelen, of Singapore, who forwarded plants of it to a London auctioneer, from whom they were all purchased by Messrs. F. Sander & Co., of St. Albans, except the plant here figured, which is in the Kew collection. It is by far the smallest of all the many kinds of *Phoenix* known, and is also exceptional in the form of its stem and in the elegance and soft texture of its bright green leaves. According to M. Roebelen it is a native of the Laos States, Siam. "It grows in great abundance along the rocky banks of the majestic river Mekong, as far north as twenty-two degrees latitude, and where the temperature descends to forty-one degrees Fahrenheit in the months of December and January. Although I looked very eagerly for seeds and flowers, I could discover none, but was told by the natives that monkeys and wildcats are very fond of the small berries, and carry them to their hiding places, where I really could discover thousands of seedlings. The stems of this exceedingly graceful pigmy Palm never attain to more than about two feet in height, and the plant generally grows in large clumps. In the Singapore Botanic Garden there exists a small example of a Palm without a stem, and resembling my Palm very much in color and shape of the leaves, labeled *Phoenix farinosa*, and of unknown origin. Whether it is the same, or a nearly allied species, I cannot say, but doubt it very much, as *P. Roebelenii* was unknown to the natives, but was much admired by those Laos living further south of the town of Luang Phrabang."

In the Kew herbarium there is a specimen of a *Phoenix* collected in 1848 by Sir Joseph Hooker in Sikkim at an altitude of 4,000 feet, and which is very similar to *P. Roebelenii* in every character except in its being stemless although in flower.

The plant here figured (see page 273) has two stems, the longer of which is sixteen inches in length by one and a half

inches in diameter. The leaves are a foot long, and the pinnæ, which are not quite regular in their arrangement along the rachis, are from five to seven inches long, shining dark green, soft in texture and curved, and not at all spinous at the tips.

Beccari in his recently published monograph of the genus *Phoenix* refers *P. Roebelenii* to *P. humilis*, var. *Lourieri*, which he describes as having very glaucescent fronds from two and a half to three and a half feet in length. He also includes under *P. humilis* such widely different plants as *P. pedunculata*, *P. Hanceana* and *P. pusilla*. However much the needs of botany may justify this lumping arrangement, it is worse than useless for horticulture. Indeed, I believe that if Professor Beccari could see living plants of *P. Roebelenii* he would almost certainly feel compelled to alter his views with respect to its botanical position.

At Kew we have all the cultivated species and most marked varieties of *Phoenix* represented by living plants, but we have nothing that comes anywhere near to *P. Roebelenii*.

From its habit of pushing up suckers freely, this Palm is likely to become soon plentiful in gardens; its abundance in a wild state, as described by Roebelen, is also likely to be turned to account by collectors.

It is one of the prettiest of the many Palms cultivated at Kew, deserving to be placed in the same category with *Cocos Weddelliana* and *Geonoma gracilis*, so useful when small as decorative plants.

Kew.

W. Watson.

Foreign Correspondence.

London Letter.

THE meeting of the Royal Horticultural Society on May 13th was a most successful one, the exhibits being numerous and exceptionally interesting. The authorities had invited exhibitors to send specimens of such flowering trees and shrubs as bloom in the open air in England at this time, and the occasion was in fact an "Arbor Day." The vast number of beautiful hardy spring flowering shrubs now in cultivation and made available for every one by the energy of nurserymen was abundantly set forth. Many gardeners were surprised to find how much richer the shrubbery and park might be made by a liberal use of hosts of beautiful flowering plants which till now were unknown to them.

There are evidences of a revival of interest in this department of gardening. Evergreens, and especially conifers, have perhaps been over-planted in the making of English gardens, the effect being much heavier and more monotonous than is desirable in a garden—an effect more properly associated with the churchyard and cemetery. The niggardliness with which good flowering hardy trees and shrubs have been and are even now employed in the composition of the out-door garden was commented upon at the meeting by Mr. W. Goldring, who had been invited by the Society to read a paper on the subject of "Spring Flowering Trees and Shrubs." He recommended gardeners and others interested to pay frequent visits to such collections as that at Kew and to the nurseries where these plants are specially grown, and to note for themselves the plants which might be employed for effect, as well as what to avoid. That such a course was desirable was proved by the plants exhibited at the meeting. Kew alone sent flowering branches of over 180 species, whilst from Messrs. Veitch and G. Paul there were collections of beautiful and interesting plants. Amongst those sent from Kew the following were the most attractive:

Amelanchier Asiatica, *A. Botryapium*, *A. Canadensis*, *A. vulgaris*, *Azalea amæna* (hardy in the neighborhood of London), *Berberis Darwinii*, *B. empetrifolia*, *B. stenophylla*, *Prunus avium* varieties, *P. chrysocarpa*, *P. oxycarpa*, *P. Mahaleb* varieties, *P. pumila*, *Cercis Siliquastrum*, *Choisya ternata*, *Cotoneaster horizontalis*; *Cratægus* of many kinds; *Cytisus albus*, now magnificent at Kew; *C. scoparius*, var. *Andreanus*, *Exochorda grandiflora*, *Genista Hispanica*, *Kalmia glauca*, a delightful little plant with rosy red clusters of flowers; *Ledum palustre* and *L. latifolium*, both ornamental and free flowering; *Leiophyllum buxifolium*, the Sand Myrtle of New Jersey; *Magnolias* of sorts; *Olearia stellulata*, a delightful little shrub with small leaves and clusters of white Aster-like flowers; *Piptanthus Nepalensis*, the Himalayan Laburnum; *Prunus depressa*, *P. pumila*, *P. triloba*, *Pyrus Maulei*, varieties; *P. Ringo*,

*O'Brien in *Gardeners' Chronicle*, 1889, vi., 475.—Roebelen, idem, 758.—Beccari in *Malesia*, iii., 382.

P. Sorbus hybrida, *P. spectabilis*, one of the best of ornamental flowered Pears; *Rhododendron Kewense*, *R. glaucum*; Ribes of sorts; *Rubus deliciosus* and *R. spectabilis*, both represented by large shrubs on the lawns at Kew, and at present thickly laden with large pure white flowers like single Roses; Lilacs of

keel of the flowers and the rich velvety maroon of the wings are most effective. The plant cannot fail to win universal admiration. It is as easy to cultivate as the type, and it flowers when only a foot high. At present it is grafted on stocks of Laburnum, but at Kew it is successfully worked on the com-

Fig. 40.—Phoenix Roebelenii.—See page 272.

many varieties; Vacciniums, *Viburnum cotinifolium* and *V. plicatum*.

Unquestionably, the most interesting and attractive plant exhibited was the new *Genista Andreana* of Continental gardens, the correct name of which is, however, *Cytisus scoparius*, var. *Andreanus*. It is simply a color variety of our native Yellow Broom or "Planta Genista." The colored drawing of it, which was published in the *Revue Horticole* last year, does not do the plant justice. The bright yellow of the standard and

mon Broom. Another name by which this new variety is known is *Genista bicolor*. It was distributed last spring from the nursery of Croux & Fils, near Paris.

Amongst the plants exhibited by the Messrs. Veitch were the rosy flowered *Ledum buxifolium*, *Cydonia Japonica*, var. *Moerloosii*, remarkable for the rich, clear red color of its flowers; *Enkianthus campanulatus*, a new introduction from Japan, not unlike *Andromeda Japonica*, but with flowers bell-shaped, rose colored and conspicuously veined, and *Cytisus scoparius*

Andreanus. The same firm also exhibited *Picea excelsa mutabilis*, remarkable for the bright yellow of its pendent young growth, and *Juniperus Canadensis aurea*, the nut-like buds colored yellow. Mr. Paul showed the white flowered variety of *Cydonia Japonica*, *Pieris (Andromeda) formosa*, a pretty flowered shrub, with panicles of white Lily-of-the-Valley-like flowers; *Prunus Sieboldii*, one of the prettiest of spring-flowering small trees, the rich crimson of the buds and rosy white of the expanded flowers being most ornamental. At Kew this plant, when in flower, is greatly admired; the European *Daphne Cneorum*, a gem amongst Daphnes, most useful for beds or as a marginal plant to borders; it is compact in habit, and produces pretty little umbels of rosy red flowers, not unlike those of a Pimelia, on the ends of the branches.

A garden tastefully planted with the best of the trees and shrubs shown at this meeting would be a perfect paradise in May.

Other plants shown at the meeting were a grand collection of *Pæonia Moutan*, from Messrs. Kelway & Son. Notable amongst them were *Fascinatus*, an enormous flower, colored pale lavender, splashed at the base of the petals with purple; *M. S. Low*, large, rich satin rose; *Beatrice*, a single flowered variety, eight inches across the cup, pure white with yellow stamens and a purple stigma. This is the most beautiful of all singled flowered Moutans. *Caroline d'Italie* is another grand variety, the flowers being large and cream colored, flushed with rose.

Calla Elliottiana is a very handsome yellow flowered variety or species near to *C. hastata* or *C. maculata*, the flower being almost as large as that of *C. Æthiopica*, but colored bright canary-yellow. It is said to have come amongst some tubers of various kinds of Calla imported from the Cape. Seedlings of it have been raised, but they have not yet flowered. This plant shared with the *Cytisus* the place of honor amongst the new plants shown. If it proves as easy to cultivate and as prolific in flowers as the old Nile Lily it will be of immense value as a decorative plant.

Amongst the Orchids the most interesting plants were *Odontoglossum crispum virginale*, with flowers four inches across and pure white save a tinge of pale yellow on the lip; *Cattleya Warocqueana*, a variety of *C. Warneri*; *Dendrobium Galliceanum*, a pale-lipped, loose-flowered variety of *D. thyrsiflorum* and *Disa tripetaloides*. This last is now flowering at Kew. It has the habit of *D. racemosa*, but is smaller in stature, and the flowers are white, spotted with purple; the spike is fifteen inches high and bears nine flowers. It is an interesting and pretty little *Disa*, and whilst falling a long way behind *D. grandiflora* and *D. racemosa* as a decorative plant it is nevertheless worth a place amongst cool-house Orchids. Apparently it is as easy to manage as the other two.

Cypripedium caudatum is variable both in the size and color of its flowers. The finest I have seen came this week from the Glasnevin Botanic Gardens. The length of the tails was thirty-five inches, of each sepal seven inches and of the pouch three inches, the width of the latter being nearly one and one-half inches. The colors, too, were much superior to what one commonly sees in this species.

Catasetum Bungerothii, var. *pileatum*. A figure of this grand *Catasetum* recently published in Sander's *Reichenbachia*, is accompanied by some observations to the effect that the name *Bungerothii*, given to this plant by Mr. N. G. Brown in 1886, must be superseded by that of *C. pileatum*, which Reichenbach had applied to the same plant some years before. I believe there is every reason for assuming that Reichenbach did do this, in fact he told me himself soon after Mr. Brown's description of *C. Bungerothii* was published that he had already named the same plant.

Notes on American Plants.

THE first to bloom of our Butterfly Tulips is the little *Calochortus caruleus* from California. It grows only about six inches high, bearing in not very long succession several white flowers with a purplish centre, three-quarters of an inch wide, with hairy bristles inside. It is quite pretty, but the flower stems are too short for cutting. Only two or three days later comes *C. Benthani*, a plant of about the same size with bright yellow flowers, a fitting companion to the first. Our plants of both were protected from the frost by a covering of leaves.

Sedum ternatum, one of the Stone Crops, is valuable in parts of the rockery. It likes shade, yet in a light soil it will thrive in open sunlight. It grows about as high as *Phlox subulata*, and like it forms dense beds so thick that nothing else can live with it. Its dense, light green foliage is pretty, and when the

small white flowers appear, which are borne on three-spiked cymes, with the spikes almost horizontal and the flowers on the upper side, the beds are quite showy.

Many persons who are familiar with the common Chickweed (*Stellaria media*), which is a noxious weed in many gardens, may hardly believe that its near relative, the Great Chickweed, *S. pubera*, can have any value as a garden plant, yet for a shady situation at its time of blooming there are few prettier plants. It forms thick clumps a foot high and more than a foot wide. All over these clumps, as thickly set as can be, are the pretty white flowers, half an inch wide, sprinkled with their reddish brown stamens. It is not inclined to spread with us, at least like *S. media*, but seems to require no special care when once established.

The Wild Hyacinth (*Camassia Fraseri*) comes from a bulbous root with long, grass-like leaves, and bearing a long, naked stem with a spike of pale blue flowers at the summit. The flowers are more than half an inch wide and the spike three inches long by nearly an inch thick. The plant is perfectly hardy, easy of culture and well worth growing.

Iris verna, now in bloom, a little later than *I. cristata*, has pretty blue and yellow flowers, but with us it lacks the bright fresh green foliage which seems as necessary as the flowers for an Iris. This may come on later, but at this season, just as the flowers open, it makes a shabby appearance by the side of a bed of *I. cristata*, planted at the same time.

Allium madidum, from the Pacific coast, grows only about six inches high and bears a small, close umbel of pretty light pink flowers. It needs protection in winter.

The Greek Valerian, *Polemonium reptans*, is a pretty plant growing over a foot high in cultivation, with an abundance of light blue flowers half an inch wide. It is easy of culture and thrives in either sun or shade.

Saxifraga Mertensiana is a small species from Oregon, six to eight inches high, with a low cyme of small white flowers a quarter of an inch wide. The little round, scalloped leaf is its principal feature of interest. These are nearly an inch wide, thick, and lie close to the ground. Our plants were protected with a thin covering of leaves last winter. Whether this would be necessary in any ordinary season or not we have yet to learn.

Smilacina stellata, one of the False Solomon's Seals, is a plant of the Lily family, not uncommon on moist banks, with short panicles of pretty white flowers and rich light green leaves. It is also a pretty plant when in fruit, and might be useful in bouquets at both the flowering and fruiting season. It likes moist, gravelly soil and should be planted in the shade unless such a situation can be given it.

The Arrow-leaved Violet (*V. sagittata*) is not generally so large a plant as *V. pedata* or Bird's-foot Violet, but it grows with it in similar situations and is a pretty species. The blue flowers have a purplish tinge which is not usually seen in the common *V. cuculata*. It likes a fine, loamy soil.

Southwick, Mass.

F. H. Horsford.

Notes on Shrubs.

IT is not an uncommon fault with the accounts of new flowering or fruiting plants which dealers offer to the public, that the descriptions are so rose-colored and alluring as to lead the unsuspecting buyer to make many an expensive purchase which he is almost certain to regret when he discovers that his new acquisition is after all no better than some old kind which he already possessed. Such experiences finally lead people to become distrustful of all the laudatory descriptions in trade catalogues. *Rhododendron (Azalea) Vaseyi* (figured in GARDEN AND FOREST, vol. i, p. 377), from North Carolina, has, during the last year or two, received a good share of praise from all who have tried it, and in this case, at least, everything said seems to be well deserved. Without any artificial protection, and exposed to the sun and to all winds, it has not been injured in the slightest degree at the Arnold Arboretum. It has withstood the test of a variety of winters, and in vigor and hardiness has proved itself fully the equal of its more northern congeners. With the exception of a few unsatisfactory and half-hardy precocious flowering foreign *Rhododendrons* whose flower-buds rarely survive our winters, and of our native *Rhodora*, *R. Vaseyi* is the earliest of the genus to bloom. In an unsheltered situation the first flowers opened about May 15th (three days earlier in 1889) and the finest development of efflorescence was reached within a week. The interval between the opening of the first and fading of the last flowers in any individual plant is ordinarily about two weeks, but sometimes several days longer. At fullest bloom the plants are quite destitute of foliage, but the large, thin leaves appear as the pretty pink corollas begin to fall. Seed is freely

produced on plants in northern gardens, and young seedlings, when well started, make a vigorous and even rapid growth.

The *Rhodora* may bloom a few days earlier than *R. Vaseyi*, and it lasts for about the same length of time. Although normally rosy purple, the color of the flowers on some plants is much paler and even occasionally almost white, a circumstance which has not yet received much attention from propagators. Except when in flower the *Rhodora* cannot be called an ornamental shrub, but it grows well in the partial shade of other shrubs or of trees in any good garden soil, and is not so difficult to transplant as its rarity in cultivation might indicate. When the full grown plants are collected in their native habitat they should be lifted in clumps with as much of the adhering soil as possible. When such care is taken the plants will continue to grow without interruption even when transferred to a much drier soil than that to which they had been accustomed.

Few people seem to know that there is a native species of Laurel which in cultivation blossoms with the *Rhodora*, but continues in bloom somewhat later. This is the so-called Pale Laurel (*Kalmia glauca*), whose first flowers expand three weeks before those of the Sheep Laurel (*K. angustifolia*) or the Mountain Laurel (*K. latifolia*) when growing side by side. It is a straggling little plant from one to two feet high, with small narrow leaves, which are shining dark green above and

grant, pinkish red flowers. In unsheltered spots these appear about the first of May, reaching fullest development and abundance in about two weeks, after which they gradually diminish in number, although good sprays of blossom may be collected up to the first week in June. Again, in July and August or later, a second, though very scattering, crop of flowers is produced among the evergreen foliage. Though sometimes subject to injury in winter, these plants well repay the slight protection necessary to secure an abundance of bloom.

Daphne Genkwa, a Japanese species, has an entirely different aspect from *D. Cneorum* when in bloom. The lilac-blue tubular flowers appear in little clusters along the branches, which are entirely free from leaves during the first ten days of blossoming. The flowers are sometimes described as fragrant, but in specimens at the Arboretum the odor is very faint and delicate when compared with that of *D. Cneorum*. Each year's experience shows that this Japanese species is quite as hardy as *D. Cneorum*, but both are of slow growth. Although the flowers of these *Daphnes* are showy and fragrant, they seem to be rarely visited by insects, and I have never known the plants about Boston to bear fruit. Two other species, however, *D. Mezereum* and *D. alpina*, of European origin, ripen seed in considerable abundance.

Arnold Arboretum.

A Stone Bridge in Wales.—See page 270.

white beneath. The flowers are about half an inch broad and usually lilac-purple in color, but, like the *Rhodora*, the color of the corollas of some plants is found to vary, and be either darker or much lighter than the type.

The Sand Myrtle (*Leiophyllum buxifolium*) is a pretty, diminutive, dark evergreen shrub, also of the Heath family, which only grows from six inches to a foot, or a little more, in height. At Boston it comes into full bloom about the third week in May. The flowers are borne in terminal umbel-like clusters, and are usually so abundant as to completely cover the plant. The unopened buds are pinkish, the flowers very small and white, but the red anthers give them all a pink effect. The white flowers of the Labrador Tea (*Ledum latifolium*) open a few days after those of the Sand Myrtle, and although appearing at a time when white flowers are abundant, they possess a peculiar charm and individuality which is so characteristic of almost every flower in the *Ericaceae*. The Sand Myrtle is a native of the sandy Pine-barren districts in New Jersey and other more southern localities, while the Labrador Tea inhabits regions much further north; but once well established, both thrive in Massachusetts when given the same conditions as to *Rhododendrons*.

Wherever *Daphne Cneorum* becomes known it is admired and appreciated for its compact little clusters of strongly fra-

Originating New Peas.

IT was long thought that natural or insect cross-fertilization of the Pea was practically impossible, but Mr. Laxton, who is known as the originator of some fifty varieties, now thinks that minute insects which appear to feed on the pollen before the flower opens do, in many cases, carry it from flower to flower. The presence of "rogues" or irregular plants is sometimes due to this agency. Great improvements have been made in Peas in point of earliness, size, productiveness, quality and dwarfness of growth. But for various reasons there is a constant tendency to revert to the old form and lose the advantages gained. This makes the continuous production of new varieties necessary in order to counteract this retrograde tendency. How new forms are originated by cross-fertilization was explained by Mr. Laxton at the famous vegetable conference held at Chiswick last autumn in the following passage taken from the report in the journal of the Royal Horticultural Society:

"Natural fertilization usually takes place in the flower of the Pea before expansion, and, therefore, in order to secure a successful cross, the operator must let his work precede this, and it will be necessary to operate two or three days prior to the opening of the flower, and when the incipient blossom is

about one-third its mature size. This is done by carefully slitting up with a scissors' point the front of the keel petal and removing the anthers before the pollen is shed, for should this have taken place in the slightest degree it will be well to abandon the operation and recommence on another flower. The foreign pollen of the desired variety can then be applied through the opening made in the keel of the flower to be fertilized, either from a camel's-hair pencil or by direct application of the ripened pollen-bearing anthers to the upper edge of the carpel. This is best accomplished by an easily acquired movement of the thumb and finger of the right hand holding the pollen-bearing flower, the keel of which, with its point inserted in the opening made in that of the flower to be operated upon, may be drawn back over the anthers, and the pollen will be delivered by a jerk or spring into the desired position. I rarely use a camel's-hair pencil in cross-fertilization, as it brings considerable risk of introducing other pollen or undesirable foreign matter in combination with the pollen to be used. After the operation has been performed, it will be desirable to pinch out the crown and all the flowers and pods on the plant except those cross-fertilized. If in conducting the operation care has been taken not to injure the organs of fructification, and these are in ripe condition, and sufficient pollen has been applied, the pod, if the weather be not too wet or moist, will probably set, and in due course ripen its complement of seeds.

"By means, however, of cross-fertilization alone, and unless it be followed by careful and continued selection, the labors of the cross-breeder, instead of benefiting the gardener, may lead to utter confusion, because, as I have previously stated, the Pea, under ordinary conditions, is much given to sporting and reversion, for when two dissimilar old or fixed varieties have been cross-fertilized, three or four generations at least must, under the most favorable circumstances, elapse before the progeny will become fixed or settled; and from one such cross I have no doubt that, by sowing every individual Pea produced during the three or four generations, hundreds of different varieties may be obtained; but, as might be expected, I have found that where the two varieties desired to be intercrossed are unfixed, confusion will be confounded, and the variations continue through many generations, the number at length being utterly incalculable. We must, therefore, still largely look to selection as the final means of obtaining permanent improvements in the Pea, and I fear the results of the recent work of Pea-crossers can hardly be fully appreciated for some years to come, during which their labors must be carefully followed by those of the seed-grower."

Notes on Vegetables.

TO-DAY (May 17th) we saw the first snap beans in Raleigh. They were of the Mohawk variety, and while the Mohawk is not so early as some other and better beans, if both have warm weather to grow in, yet the Mohawk makes its appearance first because it is better able to withstand the unfavorable weather and light frosts we have in April. So the market-growers find they cannot dispense with it. The earliest Valentines are close behind, but a difference of a few days or a week at this season of the year in a crop so easily grown as Bush Beans means all the difference between profit and loss on the crop.

If all the claims of the seedsmen in regard to new Tomatoes were true we ought to have a variety by this time which we could ripen here early in May, while the fact is that with every convenience for forwarding the crop the first week in June is as early as any can be had. There has been little or no advance in the earliness of Tomatoes in the past twenty-five years, and it may be regarded as settled that in the matter of earliness we have reached the limit. Much improvement can probably yet be made in tomatoes in the way of combining size and solidity with smoothness and earliness. In some of the recent extra early sorts there has been a retrogression in this particular, and the growers have sacrificed vigor of plant for earliness. Dwarf Champion has plenty of vigor though of compact growth. With us it has always been among the earliest, but it lacks quality for the family garden and is better fitted for shipping on account of its tough skin. We have forty varieties now fruiting.

Henderson's Succession Cabbage promises to be a very close successor to the Early Summer, and being of larger size will come in at a very good season for a summer Cabbage. But it must prove good indeed if it supersedes Fottler's Improved Brunswick in this. What we want here in the south is a Cabbage that can be safely carried through late summer and be reliable for heading in autumn and winter. The diffi-

culty in this has led to the almost universal use of the Collard, which by the by is no mean vegetable after frost has made it tender. The practice of calling any Cabbage that has failed to head a Collard has given this vegetable a bad name with those who have never tasted a real Georgia Collard. The difficulty in raising the plants in hot summer weather is one of the greatest obstacles to the raising of winter Cabbage here, and it seems to me that growers at the north or in the mountains might make a good thing by supplying the low country with plants for setting in August and September.

Since southern growers have found out that the best Potatoes for winter use and the best seed for spring planting are grown here from seed of the early crop planted in August, there has been a large development in this line, and it will not be long before the south will grow its own supply of winter Potatoes, and be able to supply unsprouted potatoes north late in spring. We will always have to buy enough of northern grown seed potatoes in spring to raise our late seed from, for I do not think the process can be carried profitably beyond one season. Formerly there was difficulty in getting the potatoes to grow which were planted in the heat of summer. This arose from the universal impression that they should be planted deep at that season, while the fact is they should be barely covered in the soil and heavily rolled. Planted thus all will grow and the soil is plowed toward them as they advance. Last fall we dug potatoes on the sixth of December which did not appear above the ground until after the middle of September, and the crop was much better than those planted late in July and which had the whole hot weather for their early growth. Late autumn is almost sure to give us good potato weather, while August is apt to be too hot and dry. Therefore potatoes planted from middle to last of August will generally surpass those planted earlier. This late crop of potatoes we consider to be one of remarkable interest to the south and at our station a series of plantings will be made this year with a view to test the best time for planting.

North Carolina College of Agriculture, Raleigh.

Cypripedium barbatum.—This species belongs to that beautiful group of "Ladies' Slippers" characterized by their marbled foliage. It forms one of the most attractive sights in the Orchid houses during May and June, during which time the beauty of the foliage and flowers is, as it were, combined. The leaves are about six inches in length, oblong-lanceolate, pale green; with darker green oblong bars marbling the upper surface. The dark purple hairy scapes are about a foot high, and usually bear one, though not infrequently two large and handsomely colored flowers, the roundish upper sepal of which forms the chief attraction. It is white above, green at the base and vertically marked with broad, dark purple stripes, while across the centre there usually extends a more or less conspicuous crescent-shaped zone of vinous purple, the richness of which distinguishes a good variety from a bad one. The margins of the linear-oblong, slightly depressed petals are thickly fringed with dark, shining hairs, a circumstance which led Dr. Lindley to apply the specific name—although one, nowadays, just as applicable to several other species, which, however, were unknown when *C. barbatum* was christened. The surface of the petals is green at the base, passing into deep purple toward the tips, while the upper margin (and sometimes the lower also) is adorned with a row of blackish shining warts. Dark purple is the color of the helmet-shaped lip, except on the pale inflexed side lobes, which are studded with small dull purple warts.

Great variation exists in the size and color of the flowers of *C. barbatum*—or, as it may be popularly termed, the bearded "Lady's Slipper"—and this fact has given rise to a host of unauthorized fancy names, which are to be found in most trade catalogues. This variation, of course, is caused chiefly by cultivation and is of like consequence in the naming. One variety, however—that known as Crossi or Warneri—is worthy of distinction, and is recognized by its paler and more densely growing foliage, and by its flowers being of an exceptionally rich color. Of course, such a plant as *C. barbatum* could not escape the toils of the artificial hybridist, whose operations with it in combination with other species have resulted in such fine hybrids as *C. Harrisianum* (the first artificial *Cypripedium* raised), *C. euryandrum*, *C. selligerum*, *C. vexillarium* and others.

It has been almost half a century in cultivation, having been introduced from Mount Ophir, near Malacca, about 1840, by Cuming, who sent plants to Messrs. Loddiges, of Hackney, in whose nursery the first flowers appeared. Since that time it has been looked upon as a very useful plant, both for decorative and exhibition purposes, and a great improvement in the

size and color of the flowers has taken place under cultivation, as will be readily seen by comparing blooms of to-day with those figured in the *Botanical Register* in 1842. The best means of producing an effect with *C. barbatum* is to grow several plants together in broad, well drained, shallow pans. A warm, moist atmosphere is most suitable, and the plants may receive plenty of water at all times, except in the cold, dreary months of the year, when very little will suffice to keep them in proper condition.

Isleworth, London, W.

John Weathers.

Moræa Pavonia.—It is just a century ago since this very desirable bulbous plant was introduced to England from the Cape of Good Hope. It is now well known in English gardens, but still scarce in this country. The somewhat weedy appearance of the plant and the straggling habit of its long grassy leaves give some excuse for this neglect on the part of those who have never seen it in bloom. The flowers measure almost two inches across, and are borne singly at the top of slender, knotted peduncles, which vary in length from nine to eighteen inches, or about half the length of the leaves, according to the size and quality of the bulbs. In general appearance they bear a strong resemblance to those of some small-flowered species of *Iris*; and, as is usual in that genus, the outer segments of the perianth are the most conspicuous. The blade of each outer segment is reflexed, and of a lilac-tinged white color, with large blotch of rich peacock blue at the base. The under side of the blade is beautifully streaked with purple, but is by no means so attractive as the upper surface. The only objection to the flowers is the brief time (seldom more than a day) they remain expanded; but they are freely produced during the spring months, and this compensates in some degree for their fugacity. The cultural requirements of this plant are of the simplest. The bulbs should be potted in fall, about six to a five-inch pot, and placed in a sunny greenhouse, or in a frame which can be secured against frost in winter. Carefulness in watering is most important, as an over-supply is dangerous at any time. After the flowering season the supply of water may be gradually decreased, and finally withheld until the bulbs are again potted. The bulbs remain in good condition if kept in the pots during the summer months, and should then have free exposure to air and sunshine, but they must be kept out. The number of plants may be increased by separating the clusters of bulbs at potting time. I lately saw a very fine collection of plants of this species grown by an amateur with no better accommodation than that afforded by a sunny sitting-room window.

There are few plants with a longer list of synonyms, a fact which perhaps may indicate its popularity in England, where the names originated. Some of these are *Iris Pavonia*, *I. tricuspidata*, *Viesseuxia Pavonia* and *V. glaucopsis*. It may be remarked that the latter genus is now included under *Moræa*. This plant is also commonly known as the "Peacock," or "Blue-eyed Peacock Iris."

Cambridge, Mass.

B.

Propagating Chrysanthemums.—On the publication of my note in the issue of GARDEN AND FOREST for January 15th on the propagation of Chrysanthemums from detached stems, one of the largest propagators of this plant wrote me that "the shoots would be good for nothing, as they would harden up, throw buds and flower prematurely." This promise does not seem to have been carried out, and I note that from my layered stems some of the shoots are as strong and vigorous as could be desired and give every promise of growing on as freely as the best of my cuttings. In one or two cases the shoots showed bud and ceased to develop, but this was not general. There was no sign of hardening up in any case. "Hardening up" is a bugbear which should not trouble any one whose plants have not been made soft and sappy in heat, and even then, if care is used in gradually exposing them to air, in planting very firmly—an important detail—and in protecting from winds, there should be no losses from this cause. This experiment seems to illustrate the fact, known to observers of the Chrysanthemum, but not often noted, that the matured stems of this plant do not under proper conditions cease their functions until the young growths have made some headway in the spring, and until those fortunately placed have made some progress toward forming independent roots, after which they decay rapidly. The old stems seem either to have some vitality stored in them, bare though they may be of foliage, or perhaps they may only be open to the flow of sap and a mere channel for the conveyance of nutriment from the awakening roots, though my experiment would seem to show that root action was not essential. The strongest shoots are shown by the Chrysanthemum as the sun

warms them into growth in the early spring (April here); and their strong tendency to form roots can be observed on those near the base of a stem but above the ground, which often throw out roots into the air. In overhauling the stock in the spring, one often finds an old stem with a shoot so far above ground as to have had no chance to root. If this is treated early like a grafted plant and buried so that the junction is covered, the shoot will soon make separate roots, and by the time the old plant loses its vigor, will be prepared to grow on without check.

Elizabeth, N. J.

G.

Clanthus Dampieri.—This is one of the most gorgeous flowered, and at the same time one of the "miffiest" of the many Leguminous plants which we owe to Australia. There are few gardeners who have not been tempted by pictures or descriptions of its beauty to attempt its culture, but the number of those who have been successful is very small. There is, however, a way to success, and that is by grafting seedlings of *C. Dampieri* on young plants of *C. puniceus*. This gets one over the water difficulty, for whilst the first named invariably goes wrong at the root, presumably through excess of water, *C. puniceus* is not so particular. The seeds should be sown in April and the seedlings cut off at the base and grafted when about six inches high. A union is effected in about three weeks.

Eurycles sylvestris and *E. Cunninghamii* are the only two species of a genus of *Amaryllideæ*, and are closely related to *Eucharis*. They are natives of Australia and the Malayan regions, whilst *Eucharis* is confined to South America. In the stove at Kew both species of *Eurycles* are in flower and they are quite ornamental enough to be classed with useful stove bulbous plants. *E. sylvestris* has a cordate leaf a foot across, a scape a foot high, and from twenty to thirty flowers in a dense umbel. Each flower is two and a half inches across, not unlike *Eucharis candida* in form and pure white. *E. Cunninghamii* has smaller and ovate leaves, and smaller flowers in umbels of from ten to fifteen. The plants lose their foliage in autumn, when they should be rested until February and then started in a stove.

Kew.

W.

Chionodoxa Lucilæ alba.—I will watch with interest Mr. Gerard's experiments with the seeds of the White *Chionodoxa*. I have tried it for two generations, and with me the seedlings invariably revert to the type.

Exochorda Alberti.—This is a very beautiful shrub, introduced from central Asia by Messrs. Albert and Eduard von Regel. It attains a height of about six feet, and all last year's growths are covered by spikes of pure white flowers, eight to ten on a spike, and about the size of large peach blossoms. Their striking appearance is heightened by the shining green foliage. It is in full flower now, on 6th of May.

Baden-Baden.

Max Leichtlin.

Correspondence.

State Control of the Gypsy Moth.

To the Editor of GARDEN AND FOREST:

Sir.—All sensible people must heartily agree with the sentiment expressed in the editorial on "Legislation Against the Gypsy Moth," in GARDEN AND FOREST for March 26th, in which legislation against insect pests is urged, and the passing of such laws as will compel careless landholders to destroy noxious insects on their properties, so that they may not be a constant menace to more thrifty neighbors. But while many people no doubt approve of legislation by the state of Massachusetts against the Gypsy Moth at Medford, a large number feel very strongly that it is impossible to accomplish the end sought. Even if the insect had extended little beyond the bounds of the district originally assigned to it, the chances for the complete extermination of the pest were very slight. But after the Act* regarding it and the appropriation of \$25,000 had been pushed through the Legislature, and the Gypsy Moth Commission appointed by the Governor had assumed its duties, it was found that the insect had spread over a territory very much larger than was at first suspected. Instead of occurring only in Medford and occupying "an area in the form of an ellipse about a mile and a half long by half a mile wide," the insect is found throughout that town and over a territory ten miles long by five or six miles in width. It is in the towns of Winchester, Arlington, Somerville, Stoneham, Melrose,

* An act to provide against the depredations by the insect known as the *Ocnervia dispar* or Gypsy Moth, and against its spreading and for its extermination, in this commonwealth.

Malden, Everett, Revere and Chelsea. It is admitted that it has got into the Middlesex Fells, a natural park dear to every naturalist and lover of nature about Boston, and there is little doubt that the pest is within the limits of Cambridge.

The greater range of the pest naturally necessitates increased expense in the attempt to control it, and it is expected that the Legislature before adjournment will grant another appropriation at least as large as the first.

Since the Commission was organized the destruction of the Gypsy Moth has been vigorously pushed. The clusters of eggs were first attacked. These were found on the trunks and larger branches of trees and shrubs, on fences, walls, buildings, piles of lumber, etc. The principal means used in destroying them was lighted kerosene torches, by which the eggs were burned in the positions in which they were found, and the trunks and limbs of the trees plainly show wherever the torches were applied. This work was begun at the end of March and was continued for several weeks. Sixty or seventy men were employed and a hundred barrels of kerosene used. In some cases it was found necessary to pull down stone and other fences in order to get at the eggs. Many acres of infested woodland have been cut down or have had all the underwood removed and burned.

Very early in May the young larvæ were found to have hatched from the eggs, and on the twelfth of the month spraying the vegetation with insecticides was begun. At present a dozen machines are at work, and this number is to be increased.

Each equipment consists of a large cask or hogshead, mounted upon a cart or wagon, a force pump and from 100 to 200 feet of hose with nozzles, besides ladders and some other accessories. The poison chiefly used up to this time is Paris Green, diluted to the proportion of one pound of Paris Green to 150 gallons of water. Five men are employed with each spraying apparatus. The law invests the Commissioners with the power to enter and work in any private property in pursuit of the Gypsy Moth. Trees, shrubs, vines and garden plants of every description are usually all sprayed, but it is not intended or thought necessary to spray grain or grass and a few similar crops. It will be necessary to do the spraying several times over in order to clear the infested ground of all larvæ, and nobody expects that the desired results will be accomplished in one season. The law imposes a severe penalty by fine and imprisonment upon any one who knowingly carries the living insects to other places. But no systematic regulations have been made looking to the prevention of the further spread of the pest. Some farmers, who carry large quantities of manure, etc., out of Medford, have had to agree to carefully examine their loads to see that none of the insects are carried out with them when they pass beyond certain limits of the town. I have not learned that any railroad train is subject to examination before leaving. There are tanneries, brickyards and other industries carried on at Medford, and many freight cars are always about either with or waiting for loads, and the possibility that in the course of the years in which it has been in the town, the insect in any of its stages has already been carried to far distant points can be understood by those who are familiar with the history of the introduction and distribution of other obnoxious animals. It is maintained by some that the sluggish habit of the large female moths is against its having spread far, and that such a conspicuous insect could not have reached other places without having been detected. But it is a remarkable fact that the Gypsy Moth, within five miles of Boston, and which must have been increasing for about twenty years, was for so long a time never noticed or reported by an entomologist or distinguished by any one from an ordinary native "moth miller."

Professor C. V. Riley's success in combatting the Cottony Cushion Scale in California by the importation of its Australian parasites, very naturally raises the question whether a little money spent in the introduction of some of the most effective parasites of the Gypsy Moth in Europe may not finally be the best way to keep it within reasonable bounds in this country.

Indeed, it is stated that Mr. Trouvelot, who is known to have been the unlucky agent in the introduction of the Gypsy Moth, had to give up all his attempts at raising silkworms at Medford on account of a fatal disease which he also accidentally introduced, and which is said to have destroyed immense numbers of other native species of insects besides the silkworms. It was supposed that the disease had destroyed all of the escaped Gypsy Moths.

If the Legislature makes further grants of money under the almost absurd idea of compassing the extermination of the pest, there is likely to be some disappointment in the results after the lapse of a few years. But if the appropriations are given with the understanding that they accomplish the tem-

porary control of the insect in the infested region, the liberal use of Paris Green is going to give Medford and surrounding towns temporary freedom from foliage-eating insects of all kinds, and, in consequence, the vegetation of the region should be the fairest in the commonwealth.

Arnold Arboretum.

J. G. Jack.

What is an Orchid?

To the Editor of GARDEN AND FOREST:

Sir.—Will some one tell me what properly constitutes an Orchid? They are "peculiarly formed," I know, but so are other flowers which are not classed with this family of *Orchidaceæ*. It was my childish belief that Orchids grew in the air only, but this error of childhood is corrected by my acquaintance with *Orchis spectabilis* and *Cypripedium pubescens*, also *Cypripedium acaule*, all three of which are now growing in my rockery. And last year I found in one of our charming lanes the *Spiranthes simplex*—Ladies' Tresses—another earth-growing Orchid.

Catskill, N. Y.

E. F. B.

[All Orchids are not "Air-plants," so called. Our native species, without exception, grow in the ground, although many of those which flourish in the tropics and which are cultivated in temperate countries under glass receive their nourishment from the moisture in the air. Plants of the Orchid family differ from all others in the arrangement of their organs of reproduction, which are united into a column composed of a single, or, in case of the Lady's Slipper, of two stamens coherent with or borne on the style or thick fleshy stigma. The perianth of the flower is composed of six divisions, arranged in two sets, each of three. The three outer divisions are called sepals, and often resemble in texture and color those of the inner set, called petals. One of the inner set of these divisions differs from the others in shape and direction, and is called the lip—the sack of the Lady's Slipper. This is really the upper petal—that is, the one next to the axis of the flower—but by a half twist of the ovary it is made to appear as if it were the lowest. These elements—sepals, petals, lip and column—varied almost without limit in form and color, combine to produce the almost infinite number of widely differing forms which are so fascinating in their oddity, quaintness and beauty. Orchids are found in all warm and temperate parts of the world, although they are more abundant in the tropics than elsewhere. They are perennial plants, often with tuber-bearing roots, and the peculiar structure of their flowers renders impossible their unaided fertilization, for which they depend on the visits of insects.—Ed.]

Planting Street Trees.

To the Editor of GARDEN AND FOREST:

Sir.—Your article on street trees recalls an example similar to the one you cite. I was engaged on some public works in a western city and was consulted by the city government about planting a principal avenue. In reply to an inquiry I stated my terms for taking charge of the work, which were pronounced satisfactory. A few days after I was informed that the city government had found a man who had offered much more favorable terms, which had been accepted. As I had to pass through the avenue every day I could watch the progress of the work. The trees were Elms, brought from the fields, eight or ten inches in diameter, and, as I learned, were furnished and planted for \$16 each. They would average twenty-five feet in height, but had been cut in so that they showed only stumps of branches, and for roots each one had a knob at the bottom which could almost have been put in a bushel-basket. There was no preparation of the ground, but the holes were dug large enough to receive the so-called roots, and the trees were stuck in and the knobs buried. This was in the spring, and 246 trees were thus planted at a cost of \$3,936. On the 31st of June of the following year only eighty-four trees showed any sign of life, and not one of them would have been suffered to remain in any properly cared for grounds. One year later only thirty-one put out a leaf here and there, and soon these were removed as worthless.

No doubt some of the members of that City Council prided themselves for looking closely after the public interests and getting the avenue planted with such fine large trees at such a low cost.

Minneapolis, Minn.

H. W. S. Cleveland.

Horticultural Society of Japan.

To the Editor of GARDEN AND FOREST:

Sir.—A meeting of this Society was held at Uyeno Park, Tokio, on the 9th of March, in the building of the Japanese Art Association, with the President of the Society, H. E. Hanabusa, in the chair. The hall was beautifully decorated with collections of rare and showy plants and works of art, among which was a model of Korakuen, a well known garden of Tokio, beautifully executed, with other equally interesting models, landscape designs, hedges, porcelain seats, stone lanterns, bird cages, stones of curious shape, and, in a word, everything needed to make an attractive garden. Choice vases for flowers, and rare pieces for tea ceremony, were also worthy of attention. Quite as praiseworthy were the flowers and works in marble to represent forms of European gardening. There were implements of gardening from the Department of Agriculture, photographs of famous European garden-scenes, and a valuable library of reference works on gardening, both Japanese and foreign. It was said that the exhibition surpassed in interest the display of the Horticultural Department of the Industrial Exhibition now open in Tokio.

The first address was by H. E. Tanaka, Vice-President of the Society, and one of the leading naturalists of the time. "Instruments of Gardening" was the subject of Mr. Ikeda, and the meeting concluded with an instructive address by H. E. Enomoto, Minister of State for Public Education. H. E. Mayeda, Vice-Minister of the Agricultural Department, was present, and during the evening Mr. Tanaka introduced a magic lantern, with many illustrations and figures relating to horticulture.

This Society promises to be a considerable factor in the horticulture of the country.

How Crops Grow. A treatise on the Chemical Composition, Structure and Life of the Plant for students of agriculture, by Samuel W. Johnson, M.A. New York, Orange Judd Company, 1890.

This is a new edition of the well known and classic work which appeared more than twenty years ago, and which, with its companion treatise, "How Crops Feed," holds the first rank among American contributions to agricultural science. Since these works were originally prepared, our knowledge of the processes of plant nutrition and of the other subjects considered in them has greatly advanced, and this revision is an exposition of the present condition of the science of agriculture—so far as it is based on the chemical composition of plants, their structure and life. As the author points out, agricultural science in its widest scope comprehends a vast range of subjects and lays under contribution almost every department of human learning. It is closely concerned with the sciences of geology, meteorology, mechanics, physics, chemistry, botany, zoology and physiology, as well as with social and political economy. The topics treated in this volume, however, are those which directly interest the farmer in his daily dealings with plants, soils and fertilizers, or, to quote Professor Johnson's words in the introductory chapter of the volume: "How the plant grows—the conditions under which it flourishes or suffers detriment—the mode of its construction and organization—how it feeds upon soil and air—how it serves as food to animals—how the air, soil, plant and animal stand related to each other in a perpetual round of the most beautiful and wonderful transformations—these are some of the grand questions that come before us; and they are not less interesting to the philosopher or man of culture than important to the farmer who depends upon their practical solution for his comfort; or to the statesman who regards them in their bearings upon the weightiest of political considerations." In this clearly defined field Professor Johnson's writings have proved not only of practical advantage to working farmers, but they have commanded the respect of men of science, and perhaps no other agency in the country has been so potent in encouraging serious research in the sciences related to agriculture and in elevating the character of agricultural discussion in the periodical press.

Perhaps one of the most important services rendered by this book has been its influence in establishing the practical value of science to the farmer—in showing him that genuine science is not something remote and fanciful, but immediately useful truth. The persons who hold that there is an essential conflict between theory and practice, and that narrow individual experience is of greater value in agriculture or horticulture than the wider generalizations of science, should study these

sentences, which are taken from the introduction to "How Crops Grow": "Science employs, in effecting its progress, essentially the same methods that are used by merely practical men. Its success is commonly more rapid and brilliant, because its instruments of observation are finer and more skillfully handled; because it experiments more industriously and variedly, thus commanding a wider and more fruitful experience; because it usually brings a more cultivated imagination and a more disciplined judgment to bear upon its work. The devotion of a life to discovery or invention is sure to yield greater results than a desultory application made in the intervals of other absorbing pursuits. It is, then, for the interest of the farmer to avail himself of the labors of the man of science, when the latter is willing to inform himself in the details of practice so as rightly to comprehend the questions which press for solution."

It is needless to add that Professor Johnson has taken care to inform himself on the points where science and practice come into contact, and that the revised edition neglects none of the important discoveries in physics, chemistry or biology which, in recent years, have done so much to aid the farmer in his legitimate work of winning from the soil at the least cost the greatest possible amount of certain animal and vegetable products.

Notes.

The new crop of sweet potatoes is beginning to come in from the south. Gooseberries, too, are now found in market, and apricots from California are already quite plentiful.

A Mr. Lathan, of Eddisburg, near Liverpool, possesses a gigantic *Camellia* twenty feet in height, as much in the diameter of the head, and thirty inches around the stem, from which he annually sells \$300 worth of flowers.

Our esteemed correspondent, Dr. Charles Bollé, of Berlin, has recently been appointed inspector of the Department of Parks and Gardens of that city, a position which will enable him to make available his great knowledge for the benefit of the public.

A Pine Forest Land Improvement Company with a capital of \$1,000,000 has been incorporated at Lakewood, New Jersey. A new hotel will be built by the association, but it is understood that it will give special attention to the preservation of the Pine lands of the county and to the planting of new tracts.

Professor Green, of the Ohio Experiment Station, recommends the use of rubber bands in bunching asparagus as less likely to injure the stalks than unelastic strings. To fit the band around the upper end of a bunch the heads of the shoots may be placed in a teacup, and the band gently slipped from the cup around the bunch.

By order of the court a Rhenish railroad company recently paid \$625 for five full grown and five young Apple-trees, which stood on a bit of ground that had been condemned for its use. Another company in Prussia was obliged, in the year 1886, to pay \$600 for a single Cherry-tree, as it was proved that its product annually sold for at least \$25.

A recent issue of the *Rural Pacific Press* contains a portrait of a remarkable specimen of Dr. Parry's *Arctostaphylos Manzanita* growing at Helena, California. It is a wide-spreading shrub separating into several branches just above the surface of the ground, where the short trunk girths eleven feet and six inches. It has attained a height of from thirty to thirty-five feet, the head spreading thirty-six and thirty feet in the two directions.

The Paulownia is flowering this year in the Public Garden in Boston, a very unusual, if not an unheard of occurrence in eastern Massachusetts, where the tree just survives, forming its flower-buds sometimes in sheltered situations, and then almost invariably losing them again during the winter. It usually flowers well in this latitude, however, and the trees in Central Park are still covered with beautiful and fragrant blossoms.

Foreign journals state that Herr Bornmüller, while exploring the districts east of the Black Sea, recently discovered a new Poplar, a natural hybrid between *Populus alba* and *P. nigra*. It resembles the former in the large sharp teeth of its leaves and in the thick white tomentum which covers the lower surface of the young leaves and twigs, while it approaches *P. nigra* in the three-cornered shape of the leaves, which later become entirely green.

Reports from Tiflis say that the phylloxera has invaded parts of the Caucasian region where hitherto it had been unknown,

large quantities of infected vines having been discovered in the province of Kutais. Radical measures are to be used to stamp out the pest, but the enormous extent to which it has already spread will render them difficult of application, and the government has arranged that experiments shall at once be made with American Vines.

Monsieur Croux, the French nurseryman, exhibited, according to a report published in a late issue of the *Revue Horticole*, an interesting collection of Magnolias before the National Society of Horticulture of France. The collection contained, besides the varieties of the Chinese Magnolias ordinarily cultivated, *Magnolia spectabilis*, with small white flowers flushed with pink; *M. hybridia speciosa*, described as similar to *M. Soulangeana*, although later in blooming; *M. Norbertinia*, the latest flowered of all the Magnolias derived from *M. conspicua*; *M. rosa grandiflora*, a seedling raised by M. Lenné, with large, handsome rose and white flowers and one of the best varieties, and *M. odoratissima*, a hybrid between *M. conspicua* and *M. Lenné* with large, rose-white, fragrant flowers.

In an article recently published in the *Fortnightly Review* Mr. Beatty-Kingston names 10,000,000,000 francs as the amount of the loss suffered in wine-growing France between the years 1875 and 1887 by the ravages of the phylloxera and fungoid pests. Now, however, they seem to have been definitely vanquished. In the Médoc district the vines have recovered themselves since 1882, when the ground around them was saturated with a solution destructive to the phylloxera; and the yield for the three past years has greatly exceeded the previous average, and, indeed, has prophesied a future yield of unparalleled richness. Last year the vineyards of Château Lafitte alone produced 1,200 hogsheads of wine, and 66,000,000 gallons were produced in the Gironde district.

The Annual Administration Report of the Forest Department (Southern and Northern Circles) of the Madras Presidency for the financial year 1888-1889 has reached us, and contains a large amount of technical information with regard to the workings of the department, with notes upon various plants cultivated on a larger or smaller scale by the forest-department. It appears that three hundred and ninety-eight square miles of reserved forests and one hundred and forty-five square miles of reserved lands have been added during the year to the areas under the immediate control of the department. The financial results of the year show a handsome balance in spite of numerous extraordinary expenses, and demonstrate the success of forest-administration in India.

In the last number of the *Revue Horticole* which has reached us the attention of cultivators of the Lilac is directed to the fact that the regular blooming of the Lilacs in the public gardens of Paris is obtained by an annual pruning, which serves also to keep the plants in shape and within reasonable bounds. Every year, after the flowers have passed, the flowering branch is cut back to the bud at its base. By this means all the strength of the plant is thrown into the branches which have not flowered. These branches then grow vigorously, and are thus able to develop the terminal buds which assure the flowers of the following year. The practice is one which might be more generally observed than it is, especially as Lilacs, unless they are pruned, occasionally grow beyond ordinary limits and do not always flower regularly every season.

Among the rare Orchids now in flower in the collection of Mr. F. L. Ames, North Easton, Massachusetts, are three varieties of *Cattleya Reineckiana*, one of the specimens with twenty and the other with sixteen flowers; *C. Wagneri*; six fine plants of *C. Warneri*; *C. Mendelii grandiflora*; *C. imbricata*; *C. Mossiæ aurea* and *C. Mossiæ Peetersi*; *Oncidium Kramerii lutea*; *Cælogyne Dayana* (seven spikes); *C. tomentosa*; *Eriopsis rutidobulbon*; *Epidendrum O'Brieni*; *Maxillaria Sanderiana*; *Dendrobium polyphlebium*; *Cypripedium Mastersi*; *C. Euryale*; *C. Curtisi*; *C. leucorrhodum*; *Odontoglossum excellens*; *Masdevallia ignea Goorei*; *M. Harryana regalis* in variety; *M. Geleniana*; *Dendrobium Falconeri giganteum* and half a dozen of the best varieties of *Lælia purpurata*, all superb plants. Here, too, is a specimen of *Cattleya Skinneri*, which is more than six feet in diameter, and bearing forty spikes, with some 400 flowers altogether.

Concerning the plant *Aristolochia Goldieana*, which has been flowering at Kew and which has been described in these columns by our London correspondent, the *Journal of Horticulture*, speaking of the beauty of the flower and its grotesque disproportion to the plant which produced it, says: "The plant might have been crumpled up into a man's hand, but the one flower it produced could not have been

perfectly concealed in a peck measure. The tube was ivory white; the spreading limb formed a huge goblet, on the outer side dull green, lined and veined with dull purple; on the inner side superbly colored with bold lines and arabesque markings of a deep purplish chocolate on a rich ground of old gold. The penciling in the throat was even more beautiful than in the cup, and the translucent texture added an indefinable charm, as though the material were of a kind hitherto unknown in the vegetable kingdom."

Monsieur E. Gilbert, discussing in the *Moniteur d'Horticulture* the early days of horticulture (L'Horticulture dans ses origines sacrées ete profanes), tells us that in the Middle Ages medlars held the first place among cultivated fruits. It was the medlar, it seems, which was used as the foundation of the preserves of Orleans known as Cotignac, which were so famous that when a French sovereign entered the town a box of Cotignac was always offered to him, and it was a box of these preserved medlars which was the first present made by the people of Orleans to Joan of Arc when she led her troops to the assistance of the beleaguered city. The medlar was used as a preserve as well as to season meats, just as cresses are used now. The introduction of the Bon Crétien Pear, which is the same as the American Bartlett, dates, Monsieur Gilbert tells us, from the reign of Louis XI., during which the venerable Francois de Paule brought it from Spain and introduced it into the royal gardens. During his fatal sickness the King asked for this fruit to quench his thirst, calling it "the pear of the good Christian," in honor of the holy man who had brought it to France. And the pear Louise-Bonne owes its name, it appears, too, to Louise of Savoy, the mother of Francis I., who first cultivated it in France.

The death is announced of Monsieur Alphonse Du Breuil in his eighty-fifth year. Monsieur Du Breuil was one of the most popular and best known authors and lecturers on the management of fruit-trees in France. He was born at Rouen in 1811, in the botanical garden of which his father was the head gardener. He commenced his career as a lecturer in the Normal School and in the School of Agriculture of his native town, where, later, he established in the Botanic Garden a remarkable collection of fruit-trees. Called to Paris, he first became conspicuously known by a course of lectures on the cultivation of fruit-trees delivered in the Conservatoire des Arts et Métiers. In 1853 the French Minister of Agriculture employed him to travel over France for the purpose of giving instruction in the cultivation of fruit-trees. This duty he performed during many years, traveling during six months in all the departments, where he trained many local instructors. Monsieur Du Breuil is best known to the general public by his "Cours d'Arboriculture," published in 1846, a work which had much success and ran through several editions and of which a résumé was published for the use of gardeners. Monsieur Du Breuil's influence must have been very great in his day, and the effects of his instruction are seen not only in the excellence of the French methods of cultivating fruit-trees, but purely ornamental trees as well, to which he devoted much attention.

The most conspicuous of the shrubs now in flower in Central Park are the various Weigelas, which are blooming in remarkable profusion. The masses of *Deutzia gracilis* are also strikingly beautiful. There are many good specimens of the Virginia Fringe-tree, a particularly fine one being on the borders of the lake near the Webster statue. The old-fashioned Snowball, with its flowers hanging in great clusters from the ends of arched branches, is still at its best, and it has no superior among later introductions. The Japanese Snowball (*Viburnum plicatum*) makes a compact bush, and is very effective for a mass of bloom, but it lacks the grace of the older plant, and can never supersede it. The white *Crataegus pyracantha* shows now to best advantage, a mass of it near the Bolivar statue being especially worthy of mention. The early flowering Tamarisks, too, wherever they were subjected to a severe pruning last year, have been uncommonly floriferous. One of the most interesting spots in the park for lovers of flowers is the great irregular mass of *Rosa rugosa* near the conservatory lake. A group of the real Scotch Broom (*Cytisus scoparius*) near the Terrace is much admired for the abundant yellow flowers, which can be seen at a great distance. An excellent place to see many of the best shrubs in bloom is along the new branch of the bridle path bordering the pool near Seventy-seventh Street; and besides the shrubbery one can here see a fine effect of the Japanese Ampelopsis on the boundary wall. Only a portion of the stone is covered, and the proper character of both stone and vine and their true relation have been retained.

The American Elm.

THE Elm-tree is dear to the heart of the New Englander. No other tree is so associated in his mind with the idea of home; it forms the most remarkable feature of the domestic New England landscape, and in no other part of the country is there a tree which occupies the same position in the affection of the people as the Elm does in that of the inhabitants of New England. The people who settled the shores of Massachusetts Bay brought with them the remembrance of the Elm-trees which were such an important and conspicuous feature in the country where they had been bred; and it is not surprising that they sought to reproduce in the new country something of the old by planting by their doors the most familiar of the English "roof trees." So the habit grew of setting an Elm-tree close by the home hewn out in the wilderness, and these house-trees, planted by the early settlers of New England or by their descendants of the early generations, are the oldest and noblest trees which have been planted by man in North America.

The American Indians were not planters of trees, but they discovered the white man's love for them, and the story is told that in Massachusetts early in the last century a party of them came to the Reverend Oliver Peabody, the pastor of Natick, and the successor of Elliott, the apostle of their race, bearing two Elm-trees on their shoulders and begging that they might be allowed to set them out before his door as emblems of friendship. The larger of these two trees was struck by lightning and destroyed ninety years afterward, when the trunk girthed twenty-one feet just above the ground. An account of these trees and of two other Elms planted by the Indians in 1753 in front of the house of Mr. Peabody's successor, the Reverend Stephen Badger, as a sign of their respect for him, appeared in the fourth volume of the *New England Farmer*, published in 1826, from the pen of Mr. John Welles.

The affection for the Elm-tree, thus early developed in the New England heart, often saved it when the land was cleared for cultivation; and when roads were made and provided with trees, as they were more generally in New

England a hundred years ago than they are now, the Elm naturally was selected to shade the traveler from the burning sun of summer. The noble stem supporting the broad head of light and pendulous branches, the delicate spray, indescribably beautiful in winter, and the abundant foliage of summer, make the American Elm one of the most desirable of road-side trees when placed in a suitable situation, and a fitting ornament to stand by the stateliest mansion or the humblest farm-house.

The illustration on page 287 shows a fair example of a typical New England Elm a century old. It has been made from a photograph taken by Dr. William H. Rollins, of Boston, of a tree planted a hundred years ago in the town of Sandwich, New Hampshire. The soil in which this tree has grown is dry and rather sterile, and the tree is not an exceptionally large one for the age, the trunk girthing only twelve feet at three feet above the ground. The effect of the poor soil is already apparent, and the leaves are smaller and drop earlier in the autumn than they did ten years ago, for the American Elm will not live to a great age or develop all its beauty in every situation. It dreads drought and starves in poor soil; its home is on fertile intervals along streams, where the deep alluvial soil is never dry and where plant food is never lacking. The Elms which grew to such great size by the farm-houses of New England owed their stature to the nourishment stolen from the neighboring garden, or to the moisture drawn from the well which their branches shaded. Thus they grew to great size and lived out their span of life, which at the best is not very great, for the Elm is a fast-growing tree, and rarely lives during a longer period than two centuries or two centuries and a half. The most vigorous of them begin to show the first signs of decay before they have seen a century and a half go by, and an Elm a hundred years old in perfect health is now difficult to find, except on some exceptionally fertile river-lands like those which border the upper Connecticut. Our Elm, therefore, being so impatient of drought, and being so dependent on abundant nourishment, is not a safe tree to plant in all sorts of soils and situations, although it has long been the habit to plant it everywhere in some parts of the country. As growth and vigor diminish insects multiply; and none of our trees suffers to such an extent from their ravages. There can be no more forlorn spectacle, certainly, than the rows of half-grown, stunted Elm-trees which may be seen in our cities and their suburbs, disfigured by the canker-worm and by hordes of other insects. The Elm is one of the best of trees to plant where the soil is deep and rich and where moisture is abundant and constant; it is one of the least desirable of all trees to set by the side of city streets, where plant-food is always lacking and where moisture is quickly carried off by the artificial drainage of road-bed and service pipes. Give it a fair chance and the American Elm will hold its own against any tree in the world in its own peculiar light and graceful beauty; but, unless all the conditions favor it, there is no tree less satisfactory, and it should not be planted unless these conditions can be supplied.

North America, or the eastern half of the continent, for no Elm grows naturally in the far west, is well supplied with Elm-trees. The American Elm (*Ulmus Americana*) ranges from Newfoundland to western Texas, and from the Atlantic seaboard to the eastern base of the Rocky Mountains. The Slippery Elm (*Ulmus fulva*), dear alike to the youthful heart and to that of the purveyor of nostrums, is widely scattered over a large portion of the eastern part of the country. In the south the Wahoo (*Ulmus alata*), a much smaller tree than the American Elm, with corky branches and small foliage, grows by the banks of streams and is now often planted as a roadside tree. The Rock Elm, known to botanists as *Ulmus racemosa*, because the flowers are produced in short racemes, inhabits the western states. This is little known still to cultivators, although of much promise as an ornamental tree, and although the wood which it produces is not equaled by

that of any other Elm-tree. The Cedar Elm of Texas (*Ulmus crassifolia*), so called, perhaps, because it grows among the Junipers (*Juniperus occidentalis*), which form a prominent feature of the vegetation of some parts of western Texas, is not surpassed in grace or in beauty of habit and of lustrous foliage by many American trees. It is a tree of medium size, and as it grows naturally in dry soil, it may be expected to flourish where other Elms would not, in regions of uncertain rain-fall like some parts of southern Europe and our Pacific-coast region. Eastern America, therefore, possesses five Elms; in Europe there are three species at the most, and, according to some botanists, only two; one of these, the tree which is almost universally called the "English Elm" in this country, although curiously enough it is not an English tree at all, having been introduced into Britain by the Romans, extends through Asia to Japan, where, and in China also, another species occurs. There are, at the most, therefore, four species in the Old World, so that more than half the Elms belong to our silva.

THE action of the Legislature of this state regarding forestry matters during its recent session, tends definitely in the direction of the acquisition of land in the Adirondack region by the state, and of the establishment of a large State Park, which shall include the sources of the principal streams of the state. The Forest Commission is empowered and required to investigate the subject thoroughly and to report its finding to the Legislature at its next session. This really places the whole matter directly in the hands of the people of the state for their decision. The result does not depend upon the Forest Commission, though its action is, of course, important and necessary. It does not depend, in any great measure, upon the individual judgment or preferences of the men who will be members of the next Legislature. It depends upon the intelligence, foresight and will of the people of the state, and very largely upon the expression of the people's interest and wishes regarding the matter through the press of the state during the coming summer and autumn.

These are the essential facts to be kept in view. The permanent maintenance of forest-conditions over extensive mountain areas around the sources of the rivers is necessary to the commercial prosperity of the city of New York, and is important to the towns and agricultural regions of the interior of the state. The Adirondack mountain, forest and lake region has an incalculable and ever increasing value to the people of the cities of the whole country as a wilderness, a land of unviolated natural solitudes, of sylvan beauty and peace. It should be forever a matchless sanitarium, a paradise for civilized anglers and hunters, an ideal refuge for escape from the burdens of toil and the fever of life in great towns. If the people of the state have the foresight and wisdom which are essential to their own prosperity they will decree whatever action and expenditure are found to be necessary for the establishment of an adequate and permanent forest-reservation around the sources of their principal rivers.

WE find the following paragraph leading the editorial column in a recent issue of *Popular Gardening*: "An English paper criticises the frequent use made of the unfortunate term 'landscape architect' by American landscape-gardeners, and thinks the word very descriptive of the formal, hateful work frequently done by them. Perhaps the criticism is not quite undeserved." We consider it altogether undeserved. Formal gardening, in the true sense of the word, as implying a symmetrical, architectural arrangement of surfaces and plantations, has rarely been attempted in this country; but the few instances where such an arrangement forms a feature in a park of generally informal character—as, for instance, the Mall and terrace in the Central Park—can surely not be described as "hateful." It is probable, however, that the English critic referred to the use of such minor formal elements as stiff

flower-beds and regular groups of exotic foliage-plants. Of this kind of work many hateful examples may certainly be found in America. Nevertheless, it is so far from characteristic of America that the American abroad is perpetually astounded by the sins of foreign gardeners. In England the newly developed love for hardy flowers has but added to the trouble, for one constantly sees shrubberies defaced by symmetrical rows of flowering plants placed along their borders; and instances of a purely natural treatment of lawns and plantations are now far rarer there than here. Formal gardening of the true sort is much better understood in France than with us; but formal features of the bad sort are there also much more universally introduced than here. In no European city, we can safely say, is there a park conceived in so purely naturalistic a way and kept so free from inharmonious details as the Central Park. The Thiergarten, in Berlin, by far the most beautiful park in Europe, cannot be compared with it, as this is rather a carefully tended and cultivated forest than an artificially formed and yet natural looking landscape. From end to end the Bois de Boulogne is defaced by immense flower-beds of shrieking colors, placed in the most inappropriate situations; the same is true of most portions of the large park of which the people of Lyons are so proud; and, in short, a journey through Europe, followed by one in this country, would convince the English critic that, whatever they may call themselves, our landscape-gardeners better deserve the name of artists to-day than those of any other land.

Trees in Their Spring Attire.

AT this season of the year we may realize more fully perhaps than at any other how deficient our ordinary text-books are in their descriptions of trees, and what feeble pictures, after all, they supply. The reason, of course, is that for the most part the botanist sees the trees in one or two stages of their growth only, or is even often compelled to confine himself to the dried specimens in the herbarium. Moreover, so rapid is the growth at this time of the year, so fugitive the appearances presented, that unless the trees can be inspected on a particular day, some characteristics are lost till the next season. The gardener or the forester who is always on the spot, and who is, or who ought to be, always on the look out, has great advantages in these respects. A few illustrations may suffice to explain our meaning.

In Richmond Park there are two Horse Chestnuts side by side, now each in the full glory of their new leafage, and each covered with flower-buds promising an early display of bloom. The two trees are at this moment, to use a colloquialism, as like as two pins. The color and stage of growth of the foliage and flower are, in fact, alike in both. Far otherwise was it a fortnight or so ago, when the buds were beginning to expand; then, the two trees were conspicuous a long way off, the one with its ruddy brown color forming a contrast to the other with its clear green hue. The explanation of the difference was easily found in the circumstance, that the expanding bud-scales of the one tree were tipped with deep brown, or even flushed with pink, while those on the other tree were mostly green.

Again, the leaf-scales or stipules of some of the Beech-trees are of a lovely shade of crimson, while in others they are dull brown. It is, moreover, worthy of notice, that in the extension shoots, which lengthen rapidly and which bear leaves only, these stipules are often most brilliantly colored; whilst on the same tree, on the short, slow-growing "spurs" bearing the flowers, and where the internodes, as a botanist would say, are in consequence contracted, the color of the stipular scales is dull brown. These differences make one wonder what purpose can be served by the brilliant coloration of organs whose functions would seem to be protective only, and which, once that office is fulfilled, fall off and wither immediately. The color in these stipules is presumably of the same nature as that which gives brilliancy to the leaves of the Purple and Copper Beeches. A similar color is observable in the stipules of the Lime, but we have not yet met with any purple-leaved Lime-tree.

The chemical analysis of the bud-scales, as determined by Professor Church, is quite consonant with their temporary and merely protective character. They contain relatively much earthy mineral matter, but little or none of the organic

compounds which are the accompaniments, and, indeed, the instruments of life and activity.

Another color-phase is presented by the Hornbeam; when its male catkins are first produced slightly in advance of the leaves, the whole tree is covered with a sheet of a pale olive or fawn color, quite unlike any other arboreal tint familiar to us, and one which rapidly changes as the leaves expand; notice also the peculiar olive tint of the Lombardy Poplar at this season.

Of the peculiarities presented by the developing buds of the conifers we have spoken on previous occasions. It must suffice to say that they form objects of great beauty, interesting and suggestive subjects of investigation for the student, and often afford the forester means of distinguishing one species from another. Too implicit confidence, however, must not be placed on these characteristics, for, as we write, we have before us shoots of *Pinus cembra* taken from two plants growing side by side at Coombe Wood; in the one the bud-scales and shoots are pink, in the other green. Foresters and woodmen are familiar with many variations of this character which rarely come under the observation of the botanist, but which are often of practical importance, inasmuch as they are often associated with differences in the quality of the timber and the degree of hardihood of the tree.

The general course of leaf development varies somewhat according to season and individual peculiarity. This season, in the neighborhood of London, the Sycamore, Horse Chestnut, Thorn, Hornbeam, Lime and Birch have unfolded their leaves in the order named, whilst amongst the later trees may be mentioned Oak, Ash, Elm, Beech, Plane and Sweet Chestnut.—*Gardeners' Chronicle*.

The Art of Gardening—An Historical Sketch.

XXI. The Mahometans in India.

WHEN speaking of the more ancient inhabitants of India I said that their gardening art may well have been affected, at least to some small extent, by Persian influence, for this was certainly the case in many provinces with their architecture; and in my last chapter, where the advent of the Mahometan conquerors was noted, it was pointed out that their art was distinctly based upon the art of mediæval Persia. It is indeed most interesting to see in the Mogul remains of Hindustan the sign-manual of Saracenic taste—which means a mere development of mediæval Persian taste—set on every building and garden, and no sign of that "Tartar" taste which shows in the architecture of the Chinese, a race of the same Turanian blood as the Moguls. The great mosques of Delhi are purely Saracenic in outline and feature, although their details are naturally akin to those of the neighboring Hindu monuments since they were built for the Mogul rulers by local Hindu artisans.

In one important point, however, the Turanian origin of the Moguls is evident. All peoples of Turanian blood have been great tomb-builders, owing to that peculiar form of primitive religion which prescribed the worship of ancestors. Wherever a Turanian people has flourished—whether in recent times or as the far-off predecessor of other races who have since dispossessed it—there we find a temple more like a palace than like a sanctuary in the Aryan or Semitic sense, and a tomb more like a shrine or temple than a mere place of sepulchre.

So it was in India while the Moguls ruled. A change of faith had banished ancestry-worship, but the passion for splendid tombs persisted. The Mahometan religion required the building of stately mosques, and the luxurious temperament that had developed in the once rude and warlike tribes from central Asia demanded sumptuous palaces. But the royal tombs of Mogul India surpass both mosques and palaces in interest, and they show us something which we have not found in studying the art of Mahometans of Arabian or Moorish blood.*

Architecture and gardening went hand in hand under the Moguls as they had under the old Hindu rulers. The mosque and the palace were surrounded with ornamental grounds, while as the environment of the tomb they were of peculiar importance. The usual process, writes Fergusson,† when a Mogul prince wishes to provide himself with a tomb, is now, as it was in earlier centuries, "to enclose a garden outside the city walls, generally with high crenellated walls and with one or more splendid gateways; and in the centre of this he erects a square or octagonal building, crowned by a dome, and in the more splendid examples with smaller dome-roofed apartments on four of the sides or angles, the other four

being devoted to entrances. This building is generally situated on a lofty square terrace, from which radiate four broad alleys, generally with marble-paved canals ornamented with fountains; the angular spaces are planted with Cypresses and other evergreens and fruit-trees, making up one of the formal but beautiful gardens so characteristic of the East. During the life-time of the founder the central building is called a Barrah Durrie, or festal hall, and is used as a place of recreation and feasting by him and his friends. At his death its destination is changed—the founder's remains are interred beneath the central dome. Sometimes his favorite wife lies beside him; but more generally his family and relations are buried beneath collateral domes. When once used as a place of burial its vaults never again resound with festive mirth. The care of the building is handed over to priests and cadis, who gain a precarious subsistence by the sale of the fruits of the garden or the alms of those who come to visit the last resting-place of their friend or master. Perfect silence takes the place of festivity and mirth. The beauty of the surrounding objects combines with the repose of the place to produce an effect as graceful as it is appropriate."

The most famous and beautiful of these Mahometan garden-tombs of India is the Taje-Mehal, at Delhi, built for his favorite wife by Shah Jehan, who reigned from 1628 to 1658. Every traveler has described it, and the camera has made its aspect as familiar as that of the Parthenon or Notre Dame. Nevertheless, we can have no real idea how it looks, for, more than any other great building in the world, it depends for its charm upon the grouping of many different parts and the union of them all with the gardens. "If the Taje were only the tomb itself," says Fergusson, "it might be described; but the platform on which it stands, with its tall minarets, is a work of art in itself. Beyond this are two wings, one of which is a mosque which anywhere else would be considered an important building. This group of buildings forms one side of a garden-court 880 feet square; and beyond this again is an outer court, of the same width but only half the depth. This is entered by three gateways of its own, and contains in the centre of its inner wall the great gateway of the garden-court, a worthy pendant to the Taje itself. Beautiful as it is in itself, the Taje would lose half its charm if it stood alone. It is the combination of so many beauties and the perfect manner in which each is subordinated to the other that makes up a whole which never fails to impress even those who are most indifferent to the effect produced by architectural objects in general. . . . When used as a Barrah Durrie or pleasure palace it must have been the coolest and loveliest of garden retreats, and now that it is sacred to the dead it is the most graceful and impressive of the sepulchres of the world. . . . The long rows of Cypresses which line the marble paths that intersect the garden are now of venerable age, and, backed by masses of evergreen foliage, lend a charm to the whole which the founder and his children could hardly have realized. Each of the main avenues among these trees has a canal along its centre studded with marble fountains, and each vista leads to some beautiful architectural object."

The Taje is still in perfect preservation, but such is not the case with the palace at Delhi, likewise built by Shah Jehan, in which the famous peacock throne of Aurung-Zebe afterward stood, a marvel to the eyes of traveling Europeans. It formed an immense group of varied and beautiful buildings, arranged in a symmetrical, yet by no means monotonous way; and to the northward of it the gardens survive, formally disposed and filled with fountains and little pavilions and kiosks of white marble. Around the great hall of this palace was carried the famous inscription: "If there is a heaven on earth, it is this, it is this;" and even to-day, we are told, when the barbarous, "civilized" European has done much to ruin the beauty of the spot, the words sound none too boastfully. It is still approached from the town by a magnificent street nearly a mile in length with a stream of water running through the centre and rows of ancient trees on either hand.

There is no sign in these descriptions of that love for picturesqueness and variety which marks the pleasure-grounds of Granada. I should hesitate to say that none but strictly formal gardens were designed by the Moguls of India, for I have not been able to find any comprehensive account of their work in this direction. But it seems probable that a love for symmetry and regularity was stronger—or at least more universal—here than in Spain. A common religion bound the conquerors of the two countries together, and in each case we see an art which was based on Perso-Arabian precedents. But climate and landscape differed greatly, and the blood of the two races was unlike. At Granada the most typical building is a palace, at Delhi it is a tomb; if we examine the

*The Moors built no tombs in Spain, and though Saracenic sepulchres of importance exist in Persia, they cannot compare in magnificence with the Indian examples.

† "History of Indian and Eastern Architecture."

features of the two; we shall see a likeness in fundamentals, but a difference in details, and, so to say, in the general spirit of the work; this difference means a greater degree of regularity and sobriety in Delhi than in Granada; and I may say once more, as is the architecture so in every land are the gardens which accompany it. The likeness yet unlikeness of the gardens of the Moguls of Hindustan to those of the ancient inhabitants of the country on the one hand, and on the other to those of the Mahometan rulers of other countries, shows with clearness that the art of gardening, no less than its sister crafts, has a historical as well as a purely æsthetic significance.

In conclusion, I want to call attention again to the fact that among the Hindu remains of the Indian peninsula are some which show an even stronger feeling for wholly natural landscape effects than we find in Moorish Spain—approaches to rock hewn temples, for instance, composed of rough boulders and irregularly growing trees. So far as I can gather these instances are exceptional. But, however rare, they have their importance, as showing that the peninsula was akin in its mental characteristics to the further east as well as to the west—as forming a transition which leads us without a break from the classic gardens of Greece and Italy to the picturesque natural gardens of the Flowery Kingdom. *M. G. Van Rensselaer.*

Selenipedium caudatum, var. *Warscewiczii*.

THE noble specimen of this Orchid, which furnished the subject of the illustration on page 285, forms part of Mr. F. L. Ames' very rich collection at North Easton, Massachusetts. It is one of the most ornamental of the genus, both in its large, bold foliage, and in the handsome flower, which always strikes a person unfamiliar with the curious forms Orchid-flowers sometimes develop as one of the most remarkable objects in nature.

Selenipedium caudatum was first detected in Peru by the Spanish botanists, Ruiz & Pavon, more than a century ago, and it has been an inhabitant of European gardens for more than thirty years, having been introduced in a living state by Mr. William Lobb, who was a collector for the Veitchs, and who traveled extensively in South America, where he made many important discoveries. The variety *Warscewiczii* varies from the typical plant in the deeper and brighter color of its flowers, especially of the petals and the labellum. This variety was discovered by the Polish traveler whose name it commemorates, on the mountains of Chuquibambilla, in Central America, where, it appears, it grows "exclusively on the tops of the highest trees at sixty or one hundred feet or more above the ground."* It is often cultivated in gardens under the name of *Cypripedium caudatum roseum*, and is by far the handsomest of the group to which it belongs.

S. caudatum is remarkable for the long, ribbon-like, pendulous petals, which, when the flower first expands, are three or four inches long, but continue growing for about ten days, at the end of which they are sometimes two feet or more long. Veitch, in his manual of Orchidaceous plants, records the fact that, from the second to the seventh-day, they have been observed to have increased in length as much as two inches each day, and that flowers have been noticed in which the total length of the petals exceeded thirty inches. This plant is also remarkable for the large size of the flowers, the upper sepal being sometimes six or seven inches long, and for the handsome markings of the lip, which is bronze-green, with the enfolded lobes ivory white, spotted with purple inside the brown or yellow-brown border which surrounds the aperture.

We are indebted to Mr. William Robinson, who has charge of Mr. Ames' Orchids, for the following memorandum of cultivation employed to develop this fine specimen, which is probably the largest in the United States:

"To grow and flower this variety with success the temperature of a Cattleya-house is needed. It should be kept well up to the light, but at all times shaded from direct sunlight. A good time to repot is immediately after the flowering period, and the compost should consist of equal parts good, fibrous peat and live sphagnum moss well mixed with a sprinkling of broken charcoal. As the roots grow vigorously provision should be made for their development. The pot or pan should be proportioned to size of plant and condition of the roots, which, before potting, should be carefully examined, and all dead or decaying parts removed, with all exhausted material from the ball of the plant.

"A strong, vigorous plant does not require so much drainage as one in less healthy condition, but this is a matter which

should always be carefully attended to. Fill the pot from half to three-quarters full of clean, broken crocks, with a few pieces of charcoal, and keep the base of the plant at the level of the top of the pot, and with a hard pointed stick fill in the compost well and firmly among the roots. The plant loves moisture, and at no time should it be allowed to get dry at the roots, particularly during the growing season. Syringing overhead twice a day during the summer is none too often, provided the house can be well ventilated."

Foreign Correspondence.

Letter from Haarlem.

HAARLEM, the centre of the Dutch bulb trade, is not only favored with a genial climate, where extremities in heat during summer, or great cold in winter, very seldom occur, but it possesses a soil which can be adapted to the cultivation of plants from regions widely differing from it and from each other in climate and in the quality of their soils. Strangers are always surprised when told what plants can be induced to thrive with us on one and the same piece of ground. Thus luxuriant specimens of your American bog plants like *Cypripedium* and various moisture-loving Lilies can be shown within a few yards from such drought and sun-loving subjects as the groups of central Asiatic Irises are well known to be. I attribute this to the excellent method for which our Dutch government has long been famous in carefully regulating at all times the supply of water in our many canals and rivers, and to the nature of our light, porous, sandy soil, which, though barren and sunburnt its surface may appear during summer, always remains equally moist and cool a few inches below the upper soil. Now by shading and more or less deep planting an almost endless diversity of conditions can easily be made; bulbs which require a thorough roasting and basking in the summer's sun are only covered with one or two inches of soil, while *Sparaxis* and *Ixias*, for example, the bulbs of which are rather impatient of even a very moderate degree of freezing, are planted deeply and very late in the season. They are in this way obliged to make their underground growth during the winter months, and are thus prevented from pushing up their tender shoots too early in spring. By careful shading a degree of moisture can be provided for the plants not by any means equaling the quantities of water contained in an American swampy tract of land, it is true, but still just enough for the well-being of the respective plants.

One of the most striking examples of what I have just said may be found in the culture we so very successfully carry out of that group of Irises to which the botanic authorities have applied the collective heading of *Oncocyclus*, and of which the Mourning Iris (*I. Susiana*) is one of the oldest and best known representatives. Travelers tell us that the Irises belonging to this group are found in some of the world's most arid countries, where an excessive heat and drought reign in summer, while during winter a degree of cold is registered which we here in our moist Holland never experience. The ground in the countries where the Irises are found becomes covered with a thick sheet of snow early in winter, and under this natural cover the tender rhizomes are happily protected, until the warm rays of the suddenly returning spring melt in a few days the winter's snow and the tracts of land which only a few weeks before seemed shrouded in death become everywhere studded and crowded with the loveliest flowers imaginable. In Holland and the greater part of northwestern Europe, however, nothing can be more capricious than the ordinary winter's weather. January last the thermometer often went up to fifty and fifty-five degrees Fahrenheit, while in March it sunk as low as to ten degrees Fahrenheit. In consequence of this many bulbs which had appeared above ground in the course of January and February had their tops completely frozen off. This did not matter much to the greater part of the bulbs in general, but to Irises of the *Oncocyclus* group, had they not been specially treated, it would have caused an irreparable damage, if not absolute death. The method followed here to prevent these Irises from running into leaf-growth too early is the following: The rhizomes are not planted earlier than about the beginning of December, and as soon as freezing weather sets in a thick layer of reeds or leaves is applied in order to prevent the frost from penetrating into the soil. The plants are thus making their roots during the dangerous winter months, and the new growths do not appear above ground before the middle of April, when they can grow on without fear of any check.

Within the last few years some very beautiful species have been added to this group of Irises, *I. Gatesii* and *I. lupina*

* *Gardeners' Chronicle*, xx. (1883), 722.

taking the lead among them. Of *I. lupina* I have now several plants in full flower and I have no scruple in pronouncing them to be among the most striking of this section. The entire flower is of a greenish yellow color, delicately veined with brownish black, the centre of the lip marked with a very conspicuous black blotch. *Iris Gatesii* has flowers the shape of

dish brown on a yellow ground, and adorned with a very conspicuous deep brown eye in the centre. The crossing of this with *I. Susiana* has probably given birth to the forms known in gardens under the names of *I. Iberica*, *I. Van Houtteana*, *I. insignis*, *I. ochracea* and others.

Haarlem, Holland.

C. G. Van Tubergen.

Fig. 41.—*Selenipedium caudatum*, var. *Warscewiczii*.—See page 284.

I. Susiana, but of a larger size and of a peculiar silvery yellowish gray color. It has also the decided advantage of being much hardier than *I. Susiana*. Among older introduced species *I. paradoxa* well deserves the epithet of wonderful, no other Iris flower presenting the same singular combination of colors and exquisite shape. It is a native of the southern parts of the Caucasus, and although it has long been in cultivation it is still extremely rare in European gardens. The standard segments of the flowers of *I. Iberica*, which may without exaggeration be called gigantic in comparison with the miniature size of the plant, are of a silvery white color only just perceptibly veined with a delicate lilac; the falls are very large, marked with red-

Cultural Department.

Notes on Shrubs.

WHEREVER the native Redbud Judas-tree (*Cercis Canadensis*) and the Chinese species (*C. Chinensis*, or *C. Japonica*, as it is sometimes called) are equally hardy under all circumstances, there can be no hesitation in selecting the exotic species as the finest of the two when in bloom. The flowers are about twice the size of those of our native species, and are produced in fully as great profusion, and the color is of a finer deep reddish purple. But unfortunately the introduced species has not yet proved hardy enough in Massachusetts

to encourage many attempts to cultivate it. However, there are plants about Boston, in exceptionally favorable situations, which have become good bushes, from eight to ten feet high, and annually produce an abundant crop of blossoms, which first open about the same time as those of our native species, usually between the 10th and 15th of May. Although *C. Canadensis* is not found growing wild in New England, it is perfectly hardy when grown from seed from its northern limits in Pennsylvania or Michigan, and it is possible that the Chinese species may prove equally enduring if grown from seed from its extreme northern range in China or Japan. When planted against a background of evergreens, or among the white flowering Crab-apples, which bloom at the same time, the leafless, flower-covered branches of the Redbud make a striking and beautiful effect.

The Redbuds are among the earliest woody plants of the Pea family to flower, but they find their contemporaries in the bright yellow-flowered Siberian Caraganas or Pea-trees (*Caragana arborescens* and *C. frutescens*). The first of these sometimes attains the size of a small tree. The pinnate, light-green, downy leaves are well expanded when the solitary short stemmed yellow flowers appear, so that the blossoms are not nearly so conspicuous as those of the Redbud, but they continue a little later in bloom. There are several described natural varieties and horticultural forms of *C. arborescens*, which differ chiefly in habit of growth or size of flowers, foliage, etc., but they do not present variation enough to make it worth while to grow them in a small garden. *C. frutescens* differs chiefly in being much more shrubby and slender in habit, and having only two pairs of leaflets, which are crowded at the end of the leaf-stalk. The early fruiting of these two species testifies to their adaptation to the short summers of the northern countries where they grow. The pods ripen about the end of the first week of July, and within a few days after maturity they burst open and scatter the small dark brown peas, which swell and germinate at once if they come in contact with moist soil. *C. Chamlagu* is a small shrub, of Chinese origin, which has slender branches, and large yellow flowers, which become reddish as they get old. It does not appear to be a very profuse flowering plant in this latitude, and it is not nearly as hardy as the preceding species. *C. Altagana* is a slender, graceful little plant, with very small leaves, having the general appearance of a miniature form of *C. arborescens*.

Nearly all of the Caraganas possess more or less developed stipular spines at the bases of the leaves. In most of the species they are short, but in *C. jubata* they are long and slender, and in *C. spinosa* they seem to reach the greatest length and sharpness. On the last species they are from one to two inches in length, and, though slender, are remarkably rigid, and capable of penetration. Being a native of Siberia and northern China, the plant is quite hardy. The flowers are yellow, as in almost all species of the genus. The leaves and branchlets are covered with a grayish down, and as the long spines extend far beyond the foliage, they give the whole plant an ashy colored appearance which is more curious than ornamental.

Arnold Arboretum.

J. G. J.

Fern Notes.

A VERY useful arrangement of Ferns may be made and a beautiful effect produced by planting out a number of species on a bench, a rock-work or other suitable place, and in this way, too, an abundant supply of fronds can be secured for cut-flower work. This last is an important item in most places, and by the adoption of the above system a larger and better supply may be had from a given space than if the plants were grown in pots. This has been abundantly proved in commercial establishments where the growing of Fern fronds for the market is now a special feature, though largely confined to a single species, *Adiantum cuneatum*, which is grown by tens of thousands for this purpose. But on many private places the amount of space available for such a purpose is quite limited, and consequently a variety of fronds will be found more useful. At the same time this particular Maiden-hair Fern must be placed at the head of the list as the most generally useful Fern now in cultivation, and this being the case, of course a larger proportion of this species should be planted than of either of the others hereafter named.

A. gracillimum is also good, its finely divided pinnæ being so graceful and filmy in appearance as to excite the warmest admiration when used among certain flowers. *A. Wiegandii*, a garden variety of American origin, is also an excellent sort for cutting, the fronds being of medium size, and when well matured lasting for several days in water. *A. Williamsii* and

A. hispidulum are also to be classed among the useful Maiden-hairs, both being very effective and having lasting qualities.

Onychium Japonicum should be included in the list, its slender, light green fronds being quite durable.

Several members of the *Pteris* family should have a prominent place, being among the most free-growing and easiest raised of Ferns. Their seedlings appear in almost all directions in a house that has been used for these plants for a few months. Probably the best of the *Pteris* for cutting are to be found among the varieties of *P. Cretica* and *P. serrulata*; *P. Cretica magnifica*, *P. Cretica albo-lineata*, *P. serrulata* and *P. serrulata cristata* being among the best. If the space at hand will permit, some of the larger sorts should be added, such as *P. tremula*, *P. argyræa* and *P. semi-pinnata*, as foliage of this description is very useful in large decorations.

Some of the *Nephrolepis* should also find a place, their long, graceful fronds being especially elegant when tastefully used among well-grouped flowers. *N. davallioides furcans*, *N. rufescens tripinnatifida* and *N. pectinata* are notably good, while the whole genus is pretty.

Davallia tenuifolia stricta and *Nephrodium otarium* (otherwise known as *Lastrea aristata variegata*) are also good Ferns for this purpose, though the last named is rather slower in growth than the preceding.

This short list may serve as a basis for an operation of this character, though numerous additions will soon suggest themselves to the interested cultivator.

The treatment to be given is very simple, the usual method being to fill a bench to the depth of five or six inches with soil—a light loam will answer, or, if the soil is inclined to be clayey, a third part of peat may be added and also some sand. It is best that the soil be not made too light by the addition of much peat, else the fronds are likely to be too soft for cutting, and in filling up the bench, of course, proper provision should be made for drainage; and, while a reasonable degree of shade is necessary, yet the house should not be made as dark as some Fern-houses are, or the result will be soft, flabby fronds, that wither almost as soon as they are cut.

Young, vigorous plants, from three or four inch pots, will be found most satisfactory, and, if planted out now, will soon become established and will furnish a large number of fronds during the following autumn and winter if planted in a house in which a temperature of fifty to fifty-five degrees is maintained.

Probably the most troublesome pest to which these plants are exposed is that of slugs and snails, by which the young fronds are eaten off as they appear; and an easy way to obviate this difficulty is by laying some leaves of cabbage or lettuce on the soil, and by the examination of these leaves in the morning and evening many such vermin may be destroyed.

Holmesburg, Pa.

W. H. Taplin.

Some American Plants.

ONE of the prettiest *Brodiaëas* we have seen came from Oregon under the name of *B. Hendersoni*. Its flowers, six to twelve, are in an umbel three-quarters of an inch wide, creamy white with a yellowish centre. A prominent dark purple stripe runs the whole length of the sepals both outside and inside. The leaves are from the base, long and narrow, and the naked stem is about a foot high. It would be useful for cutting.

Another showy little plant is the *Allium serratum*, from California. It is about ten inches high, with a naked stem and a many flowered umbel of rose-purple flowers half an inch wide. Like our *A. tricoccum* the leaves die down at time of blooming, leaving only the flower-stalk visible. It may not be hardy. Ours were covered with leaves during winter.

Calochortus pulchellus, now in bloom, has pretty nodding yellow flowers an inch wide, on short stems. The plant is low, only four to six inches high, bearing in succession two to five flowers. It is not suitable for bouquets, but is well worth growing as a garden plant. It probably needs protection in winter.

Zygadenus elegans, one of the Lily family, is a rare plant occasionally found along the northern portion of the United States from New York to Oregon, and along the St. Lawrence River to the Gulf. It varies much in height. Our plants from Oregon are only a foot high, but we have seen it on the lower St. Lawrence much taller. Its leaves are long and grass-like from the bulbous root. The naked stem bears a single panicle of from eight to fifteen erect white flowers, with a greenish yellow centre, three-fourths of an inch wide. It is pretty and useful for cutting, hardy, too, and should become better known in cultivation.

The common Wild Lupine (*Lupinus perennis*) is a very

American Elm-tree at Sandwich, New Hampshire, 100 years old.—See page 281.

pretty plant in flower. Its loose spikes of pale blue and purple flowers of various shades are often more than a foot in length by an inch and a half thick, on stems long enough for cutting. It is very common in some localities, growing luxuriantly in the poorest sandy soil—a desirable perennial a foot and a half high.

The little Star Grass (*Hypoxis erecta*) makes a pretty border plant, and grows much stronger in cultivation. Its narrow leaves are a third taller than its flowering stems. The numerous bright yellow flowers are three-fourths of an inch wide. It will grow in shade or sun, and is perfectly hardy.

Cynthia Virginica, a plant of the Dandelion family, is a foot and a half high, bearing on long, almost naked stems, two to five yellow flowers an inch wide, which closely resemble those of small Dandelions. They open in the warmest part of the day and close at night. The most of its leaves are at the base of the plant. It is found on moist banks in New York State and westward. It is easily cultivated, and may be grown in a thin shade or open sunlight.

Claytonia parviflora, though of the same genus as the Spring Beauties, is an Oregon species and flowers much later. Indeed, both of our species (*C. Virginica* and *C. Caroliniana*) have usually nearly died down before this begins to flower. Its flowers, however, much resemble those of its eastern relatives, but are a trifle paler, and are more numerous, on longer stems, and come from a tufted root, while ours are both from small tubers. It is a hardy plant, forming dense beds, and when in full bloom displays almost a solid mass of pale pink flowers. It needs a thin shade.

Baptisia leucophæa (False Indigo) is an interesting plant of the Pulse family. Its height is about a foot, and its divergent branches make it broader than it is tall. Its long drooping racemes of cream-colored flowers are very pretty. These racemes are often a foot in length, and each flower raised on a long pedicel is itself nearly an inch in length. It is a native of the western states, and should have a light soil in open sunlight.

Geranium maculatum (Wild Crane's-bill) and *G. Robertianum* (Herb Robert), two common eastern species, are in flower. The former is a much taller plant, with light purple flowers three-fourths of an inch wide, quite pretty, but not very durable, on ample stems for cutting. The latter is a strong-scented plant, scarcely half as high, with smaller red-purple flowers, which appear from the last of May until the middle of autumn. It is a pretty plant for rockeries. Both species like shade.

Geranium incisum, from Oregon, is also a pretty species, with rose-purple flowers, with darker stripes, an inch wide. The plant is usually about a foot high, is hardy, and well worth growing.

Hardy Plants for Cut Flowers.

THE Japan Anemones are usually classed among hardy perennials, though they are not reliably hardy in all sections. Even when covered in the open ground the strong flowering buds often get killed during severe winters, and by far the best plan is to lift the roots after the foliage has been killed by frost, and place them in boxes of soil in a cool cellar until spring, when they may be replanted in well-enriched soil. During dry weather the plants should be abundantly supplied with water, and they will be very different from the specimens of this queen of autumn blooming plants which are too often seen in our gardens. The type is the earliest to flower, and has bright, rose colored, semi-double flowers, which are very bright and pleasing, but the habit of the plant is poor in comparison to the pure white form known as Honorine Joubert, which is the best and most useful. The variety *hybrida* has pink flowers, and the three make a very interesting group for the flower border, and if a plant or two of *Aconitum autumnale* be planted with the Anemones it will give a beautiful dark panicle of flowers at the same time, and a group of these plants will be sure to attract attention in September and October. When lifting the Anemones, if it is desired to increase the stock (and one feels that it is hardly possible to have too much), the smaller fibrous roots may be carefully lifted and potted up, and if kept in a greenhouse during winter and grown on they will flower well the next fall.

During a favorable season the *Aconitum* ripens seed in fall, and this germinates readily if sown as soon as gathered, in striking contrast to imported seed of this genus. A collection of seventeen kinds of these foreign seeds was sown at the same time last fall, but not one of the seeds germinated. It should be remarked that *Aconitum autumnale* is perfectly hardy, and is better without protection, as this induces it to grow early in spring, when late frosts are still prevalent.

The Sunflowers are a beautiful genus, and nearly all the perennials are late summer blooming plants. *Helianthus multiflorus* is the one most common in gardens, especially the double variety; it only needs liberal treatment to bring an abundance of useful flowers in fall. It must be admitted that, though often called hardy, this is not absolutely true, and it is best to lift an old root and place in the cellar with the Tritomas, Anemones, Gladiolus, Dahlias, and such plants, that are indispensable, though tender. *H. angustifolius* is an elegant species, growing about four feet high, with much-branched flower-stems and deep green, shining leaves, and produces an abundance of flowers similar to those of *Coreopsis* and quite as useful for cutting. A colony of this plant is admirable in any place where it may be planted and left alone to take care of itself, as it seeds freely and soon becomes naturalized, and though old plants are liable to perish in winter the young ones are ready to take their places. *H. orgyalis* and *H. Maximiliani* are two species that flower late, grow tall, have graceful foliage, and may be used for cutting when few other flowers except Asters are to be found. They are both strong growers and need plenty of rich material to feed on, and this may be applied to the best advantage if the plants are lifted early in spring and replanted at once. This little trouble will be amply repaid by the vigorous growth the plants make, especially as the foliage is so pretty all the summer as a background to other plants that they are worth growing for this alone.

It is scarcely necessary to say anything about *Coreopsis lanceolata* except, perhaps, that it is the best hardy yellow Composite grown, and no one with a garden can afford to be without it, and, indeed, never will if it is once planted; for it seeds so freely and the birds are so fond of the ripe seed that wherever the *Coreopsis* is grown it is sure to become naturalized, as we have often seen it among long grass, in fields, near gardens where plants were growing. Last summer we attempted to gather seed, but the birds captured the lion's share in spite of all precautions. *Coreopsis tripteris* should have been classed with *Helianthus orgyalis*, it grows so tall. It has graceful foliage, and very fragrant flowers, which smell like the English Wallflower, and they are acceptable for house decoration in the latter part of September.

Papaver lævigatum.—Another season's trial of this variety confirms the favorable impression formed on its introduction last year. It is now profusely in bloom on some self-sown seedlings. The flowers are cupped, some four inches in diameter and of a very deep rich crimson, or, perhaps, blood-red, with black blotches on each petal; and it is with some satisfaction to be noted that they hold their own against the flaunting Oriental Poppies. The latter, with their beautiful Acanthus-like foliage and noble flowers, are among the best of herbaceous plants, but the vivid orange-scarlet flowers fairly overpower most other blooms in a garden, and care is necessary in planting them, so that they are far removed from any blue-reds especially, as the contrast is hideous. The new rose colored form will be valuable, as it might be planted in positions where the type would be inadmissible. Nature has favored us with entirely too many "blue-reds," as a collector of hardy plants discovers, especially among Phloxes, Pæonies, Aubrietias, Pyrethrums and Primulas, and great care should be exercised in planting these in a general collection where the orange-reds are in the same field of vision. Colors appear so differently to various observers that it is difficult to say which may not be pleasing to the average grower, but it would seem that the washed-out blue-reds might be banished from every garden. The deeper color, the rosy purple of the florists, is, perhaps, more admissible, but not satisfactory to every one.

Ornithogalum Arabicum is an old inhabitant of gardens, but until lately it has been comparatively little grown. It is often called Star of Bethlehem, although this name is properly applied to *O. umbellatum*. The flowers now in bloom in the open are very attractive, forming clusters of a dozen on long peduncles. Separately, they are about two inches in diameter, pure white, with a curious black ball-like eye. The bulbs, which may be secured in the fall, are not quite hardy with me, but, potted up, are kept in the cold frame and plunged in the open on the approach of warm weather. The bulbs have been sold largely for forcing, but, judging from some results seen, they do not seem reliable for that purpose. *O. nutans* is a somewhat striking contrast to above, being hardy and prolific of increase. The flowers of this variety are green, striped white, star-shaped, and bloom in a loose raceme. It comes very rapidly into bloom in the first warm days of April, and the flowers are rather fugacious, opening first on the lower part of the scape. It is a native of southern Europe, and has lately been found in Asia Minor.

Columbines are scarcely exceeded in grace and beauty by any family of hardy plants, and it is almost superfluous to dwell on their value for small and large gardens. From the earliest, *Aquilegia Sibirica*, to the latest, *A. chrysantha*, there is a long season of bloom, and in most soils the plants are long-lived. They naturalize well in semi-wild places, and even hold their own in not too dense grass. While the blooms are not very lasting, they are good as cut flowers for a couple of days. Cut with long stems, and with their foliage arranged at the base, they make graceful bouquets. Stock is readily increased from seed, from which they bloom the second year. If special varieties are desired, seed should be secured from very reliable source, as the flowers are very attractive to insects, and it is impossible to secure reliable seed where varieties are cultivated together. Where one is not very particular a German "assortment" such as is offered by the seedsmen will produce an endless variety.

Aquilegia dichlora, from Portugal, is now in bloom. As its name implies, this is a two-colored variety, the sepals being a turbid light purple, with white-tipped petals; flowers medium size and spurs about one inch long. The plant is about two feet high; foliage small and triternate. This variety is not sufficiently attractive for ordinary garden purposes.

Aquilegia alba grandiflora, Munstead variety, is a fine dwarf growing White Columbine, with charming cream-white flowers of a rather delicate texture. Spurs are an inch long and foliage light green and attractive.

Elizabeth, N. J.

G.

Sowing Seed.—Seeds of herbaceous Calceolarias, Cinerarias and Chinese Primulas should be sown at once thinly on fine soil, and not covered with soil. A good way to treat these seeds and seedlings in the summer-time is to select a north-eastern exposure under the lee of a building where a small platform can be erected about a foot from the ground. In this the seed-boxes are set. These are covered over with paper first, over which panes of glass are placed, and over all is a glass roof made of ordinary hot bed sash. This gives control of light, air and moisture at all times.

Ten Weeks Stocks.—At this moment I have a fine display of these most beautiful and deliciously scented flowers. The seed was sown on March 15th; when large enough the plants were pricked out in boxes one and one-half inches apart, transferred to cold frames and on the first week in May they were planted fifteen inches apart in soil that was well manured last year for potatoes. In transplanting, none but those showing double flowers were planted. The colors are red, white, purple, and a buff or chamois shade. They are from twelve to eighteen inches high, with several spikes to each plant. *Gladiolus* will be planted among the Stocks about the 15th of June so as to keep the bed occupied.

Correspondence.

The Fruit Outlook.

To the Editor of GARDEN AND FOREST:

Sir.—The crop predictions now current in the papers are generally most flattering. The business prospects of the country are cheering, the farmers and fruit-growers are congratulated on the promise of a bountiful harvest. The motives behind these inspiring forecasts are various, but they do not, as a rule, emanate from practical farmers themselves. It is a common practice among superficial observers to conclude that an abundant bloom is a sure forerunner of a bountiful crop. I have heard several persons remark this season on the full bloom of fruit trees, that it was bearing year, and there would be a full crop of all fruits except peaches. But the practical cultivator, while he knows that blossoms must precede fruit, also knows that these appearances are often deceitful.

There is probably no fruit crop so subject to the caprices of temperature and climate as the Peach. The mild, late fall of last year sent the trees into winter quarters full of fruit buds, but winter was a continuation of autumn. This mild and genial weather aroused the dormant buds and caused them to swell beyond their ability to withstand a low temperature. Peach-blossoms in December and January are not calculated to stand severe weather, and when these were met by the cold waves in the Carolinas and Virginia they were an easy prey, and the swelled, though unopened buds in Maryland and Delaware were largely killed. The fact that a few buds escaped on some of the late varieties was due to their more dormant condition, probably, than to their more hardy nature. When I announced the loss of the crop here I was told that the condi-

tion of things was probably not as bad as I thought, and there would be more peaches than expected. Since then these confiding ones have changed their views, and have concluded to do without peaches this year.

Of the other standard fruits the bloom was unusually abundant, never more so; some trees were complete masses of flowers, with hardly a green leaf visible. Years of observation have taught me that superabundant blossoms are not sure indications of a full crop of fruit, but on the contrary quite often result in a light crop. Ordinarily if one blossom in ten sets a fruit that arrives at maturity the crop will be abundant. This season, if one blossom out of a thousand produces fruit I shall be disappointed. The cause or causes that are responsible for such unexpected results are not altogether clear.

Possibly the trees in attempting to produce an extraordinary amount of pollen have had their ability overtaxed so as to be unable to impart to it the vigor necessary for the effective fertilization. An excess of moisture in the form of rain or fog will also seriously interfere with this work. I think, however, a low temperature is a more potent agency in preventing fructification than is generally suspected, and is really the responsible factor even if the atmosphere is clear and dry and bees are as active in making their accustomed visits.

It is to this cause, perhaps, that we owe the loss of our fruits this season; at all events fruit-growers in this part of New Jersey need not study the markets as sellers or count on much income from their Apple, Pear or Cherry crop.

Of the small fruits Currants are about half set. Strawberries promise well for a full crop now. Grapes are not yet in bloom here, hence it is too early to speculate in regard to them, and both Strawberries and Grapes have yet to incur the chances of attacks by insects and fungi. These fictitious forecasts are detrimental to the producer and consumer alike as far as their influence extends, and their publication ought to be discouraged. An honest, truthful statement of the condition of crops as they develop, rather than speculative theories in advance, would be far better for all concerned.

E. Williams.

The American Association of Nurserymen.

Fifteenth Annual Meeting.

THIS meeting was held in the hall of the Park Avenue Hotel, in this city, and its sessions occupied three days last week. About two hundred members were in attendance, and all sections of the country were represented. An admirable programme had been prepared by the Secretary, Mr. Charles A. Green, of Rochester, and carefully written papers were followed by animated and instructive discussion. The President, Mr. G. A. Sweet, of Dansville, New York, took a somewhat discouraging view of the immediate prospects of the nursery business, and he declared that no other industry employing the same capital and labor has been so poorly paid during the last fifteen years. The individual members, however, did not seem to be in a gloomy frame of mind, and altogether one rarely sees a representative body of business men whose appearance indicates greater prosperity. Mr. Sweet himself seemed to express the general sentiment when he said later that while the large profits which came to a new business in a new country can no longer be realized, there is no reason why the nursery business should not stand abreast of other legitimate industries and realize a fair return for capital and labor invested. The hope was expressed that since the Association had accomplished so much in securing equitable rates for freight, expressage and postage, something further might be accomplished in the way of combination against adventurers who demoralized the market by planting for temporary speculation. Mr. Sweet wisely added that it was for the interest of nurserymen to help on every movement which opened new markets for fruit, new appliances for safe transportation and new processes for preserving fruits, as well as to encourage the production of new varieties of fruit which would prolong the season, and to aid in increasing the general knowledge of trees and shrubs, and promoting the public taste for ornamental planting.

Among the subjects considered was the method of securing to the originators of new fruits and plants some

certain reward for their labors. The plan of a National Plant Register, as developed by Mr. A. L. Bancroft, of San Francisco, was considered too cumbersome, but some mode of registering new plants seemed desirable and a committee was appointed to consider the subject. Some of the members explained that they already used trademarks under existing laws, and that this practice protected them to a great extent.

We give abstracts of some of the addresses, and these will be continued next week.

GRAPES AS AFFECTED BY CLIMATE AND SITUATION.

This was the subject of a paper by Mr. George W. Campbell, of Delaware, Ohio, well known as the introducer of the Delaware Grape. The greater portion of the essay is herewith given.

The widely differing opinions upon the character and value of our most popular Grapes seem at first sight unaccountable. And although much may be due to the diversities of individual taste, the different estimates upon many of our Grapes from different sections of the country can hardly be satisfactorily referred to this cause alone. I have in mind the conflicting reports which I have seen upon the southern seedlings of the Riparia class—mostly from the Taylor and Elvira—which was introduced from Missouri with high commendation. Also upon the so-called hybrid varieties of Messrs. Rogers, Ricketts, Moore and others. I may also include special varieties of more recent date; notably Niagara, Empire State and Pocklington; as well as Brighton, Eaton, Woodruff Red, to say nothing of many more of less prominence.

Within my own experience, all the Riparia seedlings, such as Elvira, Missouri Riesling, Grein's Golden, and several others known by numbers, with Faith, Amber and Noah, have failed, in my locality, to meet expectations. While their habits of growth, hardiness, health and productiveness are generally good, they are decidedly wanting in the quality to render them acceptable for general use. Still, I do not feel warranted in saying that because this is my experience the same varieties may not be, in their native home, under the more genial influences of a southern sun, all that their introducers claimed, and valuable acquisitions to their list of native Grapes.

The various reports which we have of the Pocklington, Empire State and Niagara indicate to me simply this—that in some places and under favorable circumstances they are successfully grown and valuable—while in others, to which they are not adapted, or from some unfortunate surroundings, they are not. During the past season, in my reading of one day, I saw reports upon the Pocklington from two different sources—one praising it as a Grape of remarkable excellence, the other finding it so poor that he wanted to prosecute the nurseryman who sold it to him for a fraud.

Nearly as diverse have been the reports upon the Empire State. In some places it has apparently sustained the high character claimed by its introducers, in others it is reported to have failed both in the health and hardiness of the vine and in the quality of its fruit. In my locality the Empire State has been healthy in foliage, vigorous in growth, and—excepting in the past season, when it failed to ripen perfectly—the finest in quality and flavor of any white Grape I grow. In this instance the vines were probably allowed to overbear, and a cool, rainy autumn prevented their maturity.

The Niagara has sustained itself fairly well—though it will not endure our severe winters without protection. It is not as early as was represented—unless it is gathered long before it is ripe and while it is both immature and foxy—but if left upon the vine until well ripened it is a really good grape, retaining but little of the foxy taste or odor. My experience with the Niagara indicates that in localities to which it is adapted it will prove a valuable and profitable variety. The same remarks will apply to the Woodruff Red, except that the latter has proven, so far as tested, healthy in fruit and foliage, and entirely hardy in our severest winters. I still regard the Woodruff as probably the most promising red Grape for general planting yet introduced.

Of Mr. Rogers' many varieties, I will mention but one as bearing upon the points I wish to illustrate. His Number One or Goethe was introduced as a light or amber-colored Grape; and in Massachusetts, I presume, it rarely attains a deeper color. At Delaware, where I have grown it for more than thirty years, it sometimes obtains a light red or pink shade; but was always flavorless and insipid, with the exception of a single instance, when the autumn was unusually warm, and the ripening season prolonged until about the middle of October. It then attained a color as dark as the Delaware and a high flavor and good quality hitherto unknown,

thus showing that farther south, where the skies are brighter and the seasons longer, it might be a valuable Grape. This, I believe, is just what many of our southern growers find it; and the Elvira, with its kindred varieties and seedlings, are no doubt equally improved under the same favorable conditions.

Mr. Ricketts' Grapes, although many of them, as grown and exhibited by himself, were of great beauty and excellence, have not proven generally successful, and the most of them, I think, can only be grown to perfection by special care or in very favorable situations. The Jefferson has been with me one of the most successful, and among the best flavored, though sometimes rather tardy in ripening. John Snider, one of the oldest Grape-growers in southern Ohio, at Lancaster, gives the Jefferson the position of "the finest grape on the American Continent." But Secretary Williams, of New Jersey, finds the Jefferson unsatisfactory and of little or no value.

The Brighton Grape is deservedly popular in many places, but it often fails in productiveness. This must always continue, for the cause is found in its imperfect blossom, with short filaments and reflexed stamens. In favorable seasons, with bright and mild weather during the period of inflorescence, the pollen seems sufficient to fertilize and produce perfect fruit. But if cold and rainy weather prevails at this period the grapes fail to set, and few and imperfect clusters are the result. Some of the Rogers' Hybrids and the newly-introduced Moyer Grape are in the same class.

Most persons who plant a large number of different kinds of Grapes come to the conclusion that we have too many varieties. This is doubtless true as applied to any one locality; but the very kinds that do not succeed in that particular situation may be both successful and valuable in other places which are suited to their special requirements. Many of us have doubtless observed that occasionally, when we have pleasant and sunny weather extending late into autumn without unseasonable frosts or cold rains, some of the Grapes of southern origin, such as Catawba and Herbemont, and even our northern Clinton and Zoe, become rich and high flavored with a sweetness and refreshing sprightliness which are only attained in our climate in exceptionally favorable seasons, or on southern walls, or in sheltered and protected situations where they have artificially the climate and the surroundings which their origin and their nature require. The inference here is plain that in other places where such favorable conditions exist naturally the same happy results will as naturally follow.

I have probably said enough to indicate the point I wish to make: that success in Grape culture requires that varieties should be selected which are specially adapted to the locality where they are grown; and that because a Grape does not succeed in one section, it is by no means certain that it may not be both successful and valuable in another to which it is fitted naturally. I regard this matter of adaptation as one of the most important to be considered by the practical Grape-grower.

The area of adaptation is evidently much wider for some varieties than others. In our section of country the Labrusca type—including Concord, Worden, Moore's Early, Ives, Lady Martha and Woodruff—will probably be found more generally successful than any other class; but there are, doubtless, in some portions of the south, other varieties which are better adapted to their soil and climate than any of these. The Delaware Grape would probably be found adapted to as large an area as any other in cultivation, except for its unfortunate liability to mildew of the foliage; and I am not without hope that the use of the sulphate of copper remedies may so far overcome this difficulty as to permit the successful growing of this valuable variety to an extent even beyond that of the Concord by reason of its constitutional resistance to the attacks of Grape-rot.

I regard as of the greatest importance the use of these recently discovered remedies against the various maladies which have been so prevalent and so discouraging to Grape-growers. I believe that their general adoption and general use will not only greatly enlarge the area of successful Grape-growing, but will also enable us to grow profitably many of the finer and partially tender varieties in sections where it would be impossible without them.

SUCCESS WITH PEACHES.

Mr. J. H. Hale gave his experience in growing Peaches north of what is generally considered the Peach region—his home being in central Connecticut. He had observed that on high hills seedling Peach-trees lived and flourished, while trees in the valleys, which were cultivated, almost invariably, were killed in the winter or had their buds killed so as to destroy all hope of fruit. He, therefore, began an experiment in a small way, and planted some peach-pits from Tennessee.

He started his orchard on the high hills, taking pains that the ground should slope away rapidly, because he had observed that the cold air flowed down into the valley as rapidly as water would; never planting his trees on elevated plateaus, but on the steep ridges. He took pains to cultivate the soil thoroughly, and, having seen that in the neighborhood, trees which stood in land which had been enriched heavily with stable manure were short lived, he determined to make a trial of commercial fertilizers. He began to plant on thin land, using different kinds of chemical fertilizers, until he found that wherever he used potash and bone-dust his trees did well. He used no nitrogenous fertilizers except the little which was found in the bone, for he discovered that the trees which were fertilized with nitrogen, although they made a rank growth, died young. Six years ago his orchard had grown to fifty-two acres in a region where the mercury sometimes descends to twenty degrees below zero.

He prunes closely, and prunes so as to assist in thinning the fruit; that is, he does not begin to use the knife until after the trees have bloomed and begun to set their fruit, but he also thins very thoroughly afterward. In one orchard last year, after having thinned the fruit to one-half, he set men to work with orders to pick four peaches to every one they left, and as a result he had nothing but fine, large fruit. He took care to see that the fruit was picked carefully, and since his market was near by, every peach was allowed to mature fully. The peaches were very carefully assorted by women of taste and judgment, and among the first quality nothing but the very select and large and perfect fruit was gathered and carefully packed in new baskets made of white poplar, and pains were taken to have every peach from bottom to top of the same quality, with a label and guarantee to this effect, and then he asked a dollar more a basket than other sellers asked for fruit that looked as well on the top as his. Last year he picked 17,000 baskets. The best sold at wholesale from \$2.50 to \$3.50 a basket, the second grade at \$1.65 to \$2.25, and so on down to the lowest quality, and he received for his entire crop \$25,000.

Mr. Hale was asked whether his success had not ruined his neighbors, and he replied that, to the best of his belief, at least 100,000 Peach-trees had been sold in Connecticut this year, and although every one was guaranteed to be of the same sort as those that Hale planted, he suspects that 90,000 of them will die and very few of the rest will yield paying crops. He observed that so long as he bought trees from other dealers he found some trees of the wrong sort mixed in the row; and as they came from honest growers, he concluded that the mistake arose from propagating from trees which were standing in the nursery rows. In this way errors were perpetuated. If buds were invariably taken from bearing trees there could be no mistake.

THE VALUE OF PIECE-ROOT GRAFTING AS COMPARED WITH CROWN GRAFTING AND BUDDING.

Professor L. H. Bailey, of Cornell University, said that in no country but our own is nursery stock largely propagated by piece-root grafting. The advantages of this method are, that more trees can be made from a given stock; that it cheapens the multiplication of trees; that a given number of trees can be produced more quickly; that, with deep planting, cions of hardy stock will throw out roots of their own and preserve a tree even if the original root was tender. Of course, all varieties, when grafted, do not root equally well, but it is possible in this way to get what are practically own-rooted trees, for example, of the Chicasa Plum when grafted on the Peach. In this way piece-roots are good for temporary stock, as when the Quince is grafted on the Apple. Besides this, it enables us to grow rare plants of which we have no seeds or cuttings. What seem to be some disadvantages of this form of grafting are that the roots always grow more pronged and not so deep; fewer fine roots are thrown out, and most of them start on one side; trees from such stock (it is said) are more liable to blow over, and Professor Bailey cited as examples two contiguous orchards, one of crown grafted trees and the other of trees from root-grafts, in which it seemed clear that the latter needed staking more firmly in order to keep them upright. As a rule, root-grafted trees make a smaller growth, and Professor Bailey exhibited some photographs which seem to show that two-year-old budded trees were as large as three-year-old root-grafted trees. Professor Bailey explained, however, that these pictures were not conclusive evidence, since they were not grown by the same persons and for several other reasons. Again, root-grafted trees tend to be more crotched and straggly in the top. It is also said that they are not so long lived.

The advantages of crown grafting on whole roots or budding are that larger trees with deeper and more symmetrical roots are secured; that the young trees have greater force behind them in a more perfect root system so that they are more vigorous and growthy. It is argued also that the crown is the best place to graft because it has a more dense tissue than the root and probably therefore will make a more perfect union.

Mr. Albaugh, of Ohio, enforced the views of Professor Bailey by saying that in the experience of his company, which is very large, they have lately succeeded in getting more and better trees from crown grafts, so that they think the method is preferable both for the nurseryman and planter. At all events they never have any block of trees failing utterly, as they formerly did when they used root grafts.

A nurseryman from Nebraska declared that the question was a sectional one; that in the east, where a very strong growth was needed, whole roots were the best, but in the deep, rich soil of the west these long, strong growths failed to ripen up, and in consequence winter killed. Therefore, root grafting was the best in the west because such plants only grew to a moderate size and ripened well to the tip. He also never had found any lack of lateral roots and the trees from root grafts stood as stiffly as any others.

NEW VARIETIES OF FRUITS.

Mr. H. E. Van Deman, pomologist of the Department of Agriculture, delivered an informal address upon this topic, from which we make some extracts:

Many good varieties of Plums had come, he said, from *Prunus Americana*, which extends all through our north and northwest regions. Among the newer varieties, the Hawkeye, from Iowa, is the best. It is the largest and most beautiful, although it is late, ripening six weeks after the ordinary Plum season. Cheney, from Minnesota, is another plum of medium size, very early, of a deep crimson color, but not so good as the Hawkeye when it is cooked. Ludlow is flat in shape, large, productive and of very pleasant flavor. Rollingstone is small, of a purplish red color, handsome and well-flavored. Leduc is a very pretty, small, yellow plum, originating in Minnesota. It is very productive and sweet, and will be valuable for a dessert fruit. Hopp is of medium size, dark, solid and very sweet. Clyman is a variety of *Prunus domestica*, and is as early as the Wild Goose, six weeks earlier than the ordinary Plums of this class. It sets full of fruit, and will probably be hardy in the middle states.

Among the Japanese plums, Botan is said to be hardy enough to ripen as far north as Connecticut. In shape it resembles the Kelsey. Ogon is yellow, nearly round, and as large as the Wild Goose. Kelsey is very large, three inches in diameter, purplish, heart-shaped; but it will not fruit north of Tennessee. Burbank is of medium size, crimson-purple in color, exceedingly beautiful, rich in flavor, and it will perhaps prove hardy in the middle states. Satsuma is smaller than Kelsey, but as large as the common plums. It is round, with dark red flesh and a small stone. One disadvantage of all Japanese Plums is that they bloom so early their blossoms are liable to be caught by the frost, as in the case of the Apricot. They all hold their foliage well, and this fits them to the vicissitudes of our very trying climate.

Of the newer Pears, the Krull, originating in Missouri, seems to be the best of winter Pears. It surpasses the Lawrence in quality and color. The Idaho has not been overrated as to quality, but as yet we have no warrant for believing that it is superior in hardness to many others.

Among Apples, the Garfield, originating in northern Illinois, seems to be hardy in that trying region. It is not so large as Ben Davis. It has a brilliant crimson stripe on a yellow ground, rich and handsome in appearance and fair in quality. Lacon is of about the same quality, yellowish, and its hardness would seem to warrant trying it in the northwest. Shirk originated in Indiana. It is very sweet and of a high color. The tree is a fine grower, and it is an excellent fall sweet apple, and hangs well on the tree. Bullman has been widely advertised, but it seems to be a synonym for the Red Canada. The Pepper is a seedling of Pewaukee and is very promising. It is of medium size, red, white fleshed, a natural seedling, and is very hardy. The Foundling is an old variety of New England origin, which has been strangely overlooked until late years. It is quite hardy in the northern part of New England; very pretty, with red stripes on a yellow ground, and keeps late into the winter.

Of Strawberries the only new variety spoken of was Pearl, which is said to be one of the best, with berries of good size and held well above the ground on strong stems. It seems adapted to different kinds of soils.

Among nuts mention was made of many good varieties of our wild Chestnut, some of which are of excellent quality. One named Dupont, from Delaware, is very large. A rich tree often yielded nuts to the value of \$30 and \$50 a year.

The Paragon, which has been sent out by Engle & Son, of Marietta, Pennsylvania, is larger yet, four or five times as large as the ordinary Chestnut. It bears enormously and at an early age. It is not quite so well flavored as the finest of the small Chestnuts, but it is of purely native origin and well worthy of cultivation.

Of the newer Grapes, the Lyon, originating in Michigan, was reported of fine quality. The vine is very vigorous; the clusters are of the Catawba shape, although the berries are smaller. Colrain, which is probably a seedling of the Concord, is a variety larger in bunch and berry than Martha, and earlier. The vine is stronger and as healthy as the Concord.

Mr. Campbell, in reply to the inquiry as to whether its skin was too tender for shipment, stated that it was no more tender than that of the Worden. The Woodruff Red has proved itself a rampant grower and very productive. It is not of the finest quality and has a rather thick skin, but it is an excellent popular market variety. Green Mountain is a strong vine, very fruitful and is probably the earliest white Grape of good quality. It is rather small in berry, however.

The Crandall Currant is a variety of the Missouri Currant and the largest of the wild varieties. It originated in Kansas and has the merit of being proof against the attacks of the Currant-worm. Nor do the leaves fall as they do from many other varieties of Currant from some unknown fungus growth.

Notes.

Peaches from California are now coming into market here, and so are the sour "English" Cherries from the south.

Le Jardin, commenting upon the poisonous properties of *Primula obconica*, says that the common European Primrose will irritate and burn the lips if bitten.

It is announced in some Oregon papers that an excellent syrup, clear and well flavored, has been made from the sap of the Vine Maple (*Acer circinatum*).

Magnolia hypoleuca is just coming into bloom. Remarkably beautiful flowers of this species and of *M. parviflora* were shown at the Nurserymen's Convention last week by Mr. S. B. Parsons.

Professor Oliver, after a connection of thirty years with the herbarium of the Royal Gardens at Kew, of which for many years he has been the curator, retires from office. He is, however, to continue to reside at Kew, and will continue to edit Hooker's "Icones Plantarum," in which the most important and interesting of the new plants received at the Kew herbarium are figured and described.

The statement is made in an interesting article on the forests of Roumania, recently published in the *Revue des Eaux et Forêts*, that the American Locust-tree (*Robinia Pseudacacia*) has been used with great success in that country in holding the shifting sand at several places along the banks of the Danube, and that during the last five or six years twelve or fifteen thousand acres have been covered with plantations of this tree for this purpose.

There is wisdom as well as charity in the following words spoken by Mrs. Helen V. Austin at a recent meeting of the New Jersey Horticultural Society: "We are often told that if fruit-trees were planted in the street the boys would get the fruit. That would be one great object in thus planting, so that the boys and girls could get the fruit. The fact is that children are starving for fruit; and what with the scarcity of the article and the enclosures surrounding what there is, the average boy is forced into being a thief."

The *Revue Horticole*, quoting from the *Botanisch Jaarboek*, calls attention to the results of a curious series of experiments lately made in the Botanical Garden of Ghent for the purpose of determining whether the seeds which germinate the most rapidly produce the most vigorous plants, and whether, in the case of the Gilliflower, as had been affirmed by Dr. Nobbe, the plants which germinate first produce a larger proportion of double flowers than those in which the germination had been retarded. It appears that these experiments confirm the truth of the assertion. Such experiments, to be at all conclusive, must, of course, be repeated over and over again and on a very large scale; still, as Monsieur André suggests, they may be of immense horticultural significance.

The May issue of the *Bulletin of Miscellaneous Information* from the Royal Gardens at Kew contains correspondence on Lagos rubber, the product of the West African *Ficus Vogelii*; on a new Mealy Bug which has proved a troublesome and destructive pest among cultivated plants in Egypt, with a description and figure of the insect (*Crossotoma Egyptiacum*); on the machines used in the manufacture of hemp in the Mauritius, and on the Siberian perennial flax, about the use of which the authorities of Kew have endeavored to obtain some information in the hope that it might prove a substitute for the common Flax, which is an annual and therefore has to be raised from seed every year. The perennial Flax has numerous wiry, slender stems about one or two feet high. Many attempts have been made to utilize this plant for fibre and in the production of linseed oil, and it was supposed that it had been used for this purpose in Siberia. The correspondence, however, which Mr. Morris' inquiries have brought out, seems to show that it is doubtful if Flax on a commercial scale is anywhere produced except from the annual species.

The *American Agriculturist* for June gives an interesting account of the cultivation of Lima Beans in Ventura County, California, where the crop brings something like half a million dollars. The seed is planted in May by machines, which drill in three or four rows at a time. The plants are cultivated once or twice and never irrigated. No poles are used, but the vines cover hundreds of acres, clinging close to the ground like a green carpet. In August, when the beans are ripe, a V-shaped knife, with blades five or six feet long, and attached to a wooden sled, is drawn by three horses, which are guided between the rows by one man. Two rows are cut at once, and four men are kept busy raking the loosened vines into heaps to dry. Twenty acres are cut in a day. Three or four weeks are required to properly dry the beans, which are then run through a thresher, and the straw is stacked, to be used later as fodder for cattle and sheep. The average yield of Limas is 1,800 pounds to the acre, and these are worth \$44 at wholesale. A liberal estimate for expenses, including seed, planting, cultivating, cutting and harvesting, is \$8, leaving a profit of \$36 to the acre.

It is well known that the larvæ of the May-bug or Dor-bug do an immense amount of damage by eating the young roots of grasses, Strawberry and other delicate rooted plants. In France, especially, their ravages have resulted in great losses, and energetic attempts to destroy them are made. The destruction of these beetles is a matter of such importance that a word, "Hannetonnage," has been coined to express the action of hunting them. It appears, according to the *Revue Horticole*, that during the year 1889 the Department of Seine-et-Marne paid no less than 113,000 francs in prizes for the destruction of the beetles, which were collected to the amount of more than 500,000 pounds. They are trapped by suspending lights over shallow vessels of water. The beetles fly against the glass covering of the lamps and drop into the water below, and are then collected and destroyed. The experiment has been tried in this country with success, and it is worth doing on a large scale wherever these insects abound. As the presence of the larvæ is not known until the damage which they inflict is completed, the only way to attack them is to trap the beetles. A little kerosene-oil poured on the water placed in the vessels into which they are intended to fall will deprive them of all chance of escape.

It is well known that the practice of removing the flower-stems of Hyacinths and Tulips just as the spikes have attained full development prevails in all the bulb-farms of Holland. The general opinion is that there is but one object in view in depriving the plants of their beauty at its zenith—namely, to save the plants the strain of ripening seed, and to aid the development of the bulbs by the power thus conserved being devoted solely to them. It is recently stated, however, by a correspondent of the *Journal of Horticulture*, that one of the largest growers and exporters at Haarlem gives another explanation of the custom. The specific object of removing the flowers of Hyacinths and Tulips is, he says, to prevent the petals falling upon the leaves, which occasions spotting, commonly called "fire." When the foliage becomes thus affected its powers of assimilation and elaboration are materially curtailed, and the bulbs are greatly weakened. The strain of ripening seed is so small a consideration that in the case of Crocuses and Narcissi, which do not become "fired" by the falling flowers, it is not thought worth while to sacrifice the time necessary for removing the latter, and they are consequently allowed to fall. The manner of removing the flowers is merely a matter of convenience. Hyacinth spikes are cut off; Tulips, the stems of which are brittle, are broken with the fingers and thumb.

RECENT numbers of *The Forum* and of *The Country Gentleman* have contained articles from Mr. C. Wood Davis, a Kansas farmer, which attempt to show that the arable lands of the public domain have been so rapidly taken for agricultural use during the past twenty years that they will be completely occupied at a much earlier date than has heretofore been deemed possible. The fundamental reason generally given for abandoned farms in the east and

depressed agriculture in general has been the rapid expansion of the cultivated area of the country, and therefore the increase of staple farm products beyond the home demand for them. Whether certain prosperity awaits the farmer as soon as the country will consume all that he can produce is not a question to be discussed here, but the figures which indicate that we shall be compelled to import wheat before the end of the century are interesting.

It is probable that Mr. Davis underrates the productive capacity of our total farm area, but after making due allowance for this we are prepared to believe that his prophecy is worth considering. Our people have acquired a habit of boasting of the country's ability to feed the world and of our exhaustless wealth in general. But natural resources are not infinite. A few years ago we were talking of our exhaustless wealth of timber, but our forests of White Pine, the most important timber-tree of the continent, are no longer spoken of as boundless; dealers in hard-wood know that the supply of Walnut and Ash will not endure forever, and there is a growing belief that the Long-leaved Pine is doomed. In like manner we may soon discover that good land can no longer be had for the asking, and that every acre which can profitably be tilled, even with the help of irrigation, has been brought under the plow.

American Dried Fruits in Foreign Markets.

TWO complaints have been made against the healthfulness of American dried fruit. The first is that when this product is sulphur-bleached there is a question whether the after-drying removes all traces of the sulphur, and therefore whether the fruit has absorbed and retains enough sulphuric acid to impair its healthfulness and flavor. The other objection is that when fruit is dried on galvanized wire trays it takes up a sufficient quantity of zinc to make it poisonous. Very careful chemical tests made in this country have failed to secure any proof of the presence of free sulphuric acid, and Dr. Lattimore, in behalf of the New York State Board of Health, after testing numerous samples of the evaporated fruit, found no trace of zinc. Nevertheless the exclusion of our fruit from certain European markets particularly on account of alleged danger from zinc is a serious matter to producers. The fact seems to be that traces of zinc have been discovered in exported fruits, and although the quantity was so minute as to be utterly harmless, this serves as a pretext for shutting out our fruits from foreign markets, and therefore any remedy or any method of evaporation which will leave the dried fruit absolutely free from foreign substances is much to be desired. We add a portion of an interesting paper which was read by Mr. Michael Doyle, of Rochester, at the meeting of the Western New York Horticultural Society last winter, and which has been published in the proceedings of that meeting:

The agitation against evaporated fruits commenced in 1884 in Holland, and since then has spread to Germany, the largest consuming country in Europe, and later to the other adjacent countries. It is claimed by the health authorities that evaporated apples contain minute portions of the oxides of zinc to an extent more or less deleterious to human health. Not a single case of illness resulting from a proper use of this fruit has ever been reported in this country or the United Kingdom, notwithstanding the fact that tens of thousands of tons have been manufactured and consumed since the business began some eighteen years ago. The effort on the part of the German government to prevent the importation of this class of fruit has been based largely upon the desire of excluding it, for the object of encouraging the manufacture of the same class of goods in Germany. Only a few years ago the Hanoverian government gave the sum of 50,000 marks, say \$12,500, for the establishment of an evaporating factory, the first of its kind in that country. The promoter of the scheme did not, however, calculate with much accuracy upon the large quantity of fruit required to keep the factory in steady operation, and he found it impossible to secure a sufficient supply. Besides, the cost was so much above the value of the product when offered in competition with fruit shipped from this country, that the manufacture was only continued by drawing on the subsidy

of the government to cover the loss. In other words, fruit was offered from here at about seven and a half cents delivered at Bremen, while that made at Hildesheim cost fully ten cents per pound. As a result, the evaporator was operated until the donation of the government was exhausted, then stopped, and it has not since been reopened; for the German experimenters have found to their satisfaction that, in the present condition of orchard-culture in their country, they cannot compete profitably with America. This we believe to be the beginning of the alarm in that country over American apples.

It is safe to say that there is no more danger in fruit dried upon galvanized trays than there is from the employment of the ordinary tinned cooking utensils. At present it is almost impossible to do business with Germany without furnishing a sworn declaration as well as a chemist's certificate, attested by the Consul at New York, declaring and showing that the goods are absolutely free from zinc or zinc oxides. Goods which are found to contain even the most minute quantity are confiscated by the Government officials and their value destroyed by pouring crude petroleum on the fruit, which renders it unfit for food. As a result the business is done with no little hardship, and many houses in Hamburg and Bremen have abandoned the sale of American fruit, as the penalties, not only in the way of confiscation of the fruit, but of heavy fines and long imprisonment, are sufficient to make the dealers extremely careful and cautious in handling the product.

But although our fruit contains no injurious amount of zinc, we must prepare it absolutely free from every trace of the metal or we can make no sales. Fruit dried on wooden trays, or those made from netting, is absolutely free from zinc. Recent analysis has shown this; and although the change was made at a rather inopportune time, and rather late in the season, the quantity of fruit produced and dried on those trays was quite considerable, all of which has been taken without objection abroad. A prompt improvement is necessary, either by greater care in the use of galvanized trays, for it has been shown that the small particles of zinc found in the fruit have been caused by the use of the iron scrapers used in removing the fruit, which very often adheres to the wire, or by ceasing to use them. The use of these sieves for three seasons has shown a loss of twenty-four per cent. of the weight of the zinc galvanism by this means alone. In order to retain the trade established many years ago on the Continent it is imperative that some other system be employed, for it is only by abandoning the galvanized trays that the prejudice necessarily created against the product can be successfully overcome.

There is room for inventive genius in this direction, and proper remuneration will attend the successful efforts of the man who will offer to the manufacturers a satisfactory substitute for the galvanized wire now employed. It should possess fire-proof qualifications if of either wood or netting, and if metallic it should not be liable to oxidation and should not discolor the fruit. Just now this is the only impediment to increased trade abroad, which will undoubtedly follow these much needed improvements in the manufacture, and all fruit growers should be interested in pushing the industry to its maximum development, and thereby assure a remunerative outlet for our constantly increasing orchard-products.

Parterres in the Park of St. Germain.

NO more delightful place than St. Germain en Laye can be reached in a day's excursion from Paris. For generations the ancient palace and the adjacent forest were favorite resorts of royalty on pleasure bent, and the strong walls of the former frequently served as a safe place of retreat for one court faction or another especially during the wars of the Fronde. A so-called "New Palace" was built by Henri IV., but nothing now remains of it except some portions of its terrace walls and the pavilion called by his name. Adjoining this last is the magnificent terrace for the sake of which and the view that it affords the tourist now seeks St. Germain. It was constructed by Le Nôtre during the reign of Louis XIV., measures 12,500 yards in length by about forty yards in breadth, is planted with avenues of great trees, and commands a wide and beautiful panorama, with the winding Seine as the central feature and Paris far off in the distance.

In addition to this terrace Le Nôtre laid out extensive gardens at St. Germain and ornamented them with fountains and statues. But they have entirely disappeared. The garden shown in our picture is a modern creation and occupies a different site, a portion of the forest having been cut to make room for it. The forest fills a promontory formed by one of the bends of the Seine, and the trees it contains are chiefly

Oaks, Elms, Chestnuts and Hornbeams. Lacking the picturesque wild charm of the Forest of Fontainebleau, it has a sober and massive beauty of its own, with its dense growth of trees divided at regular intervals by straight avenues and alleys. It contains several small buildings, among them one called *Les Loges*, which is a government school for young girls. From this building the view we present (see page 299) is taken, showing another adaptation of that system of planting called "French parterres," to which we have several times referred during the past few months. Seen in connection with the building itself, the effect of such formal planting is, of course, better appreciated; but the picture shows how well it has been joined to the forest beyond. If this had the varied natural aspect we find at Fontainebleau, its association with a formal garden would have been less justifiable; but here, where it is formal itself in character, an appropriate garden foreground for a dignified structure has been secured with no violation of the laws of harmony.

Pinus glabra.

LOCAL in its distribution, and sparsely scattered amongst the rich and varied tree growth of the heavy forests in the southern states east of the Mississippi River, the Spruce Pine has until recently been but little noticed. It was described by Walter more than 100 years ago, but for the next seventy years it escaped the attention of botanists, when it was rediscovered by Mr. H. W. Ravenel, most probably in the same district where it was found in the coast region of South Carolina by the first investigator of the flora of that state. Subsequently Dr. Mellichamp observed the tree in several other localities of the coast near the southern limits of the state. About ten years later it was found by Professor Hilgard in the south-western part of Mississippi on the banks of the Pearl River, then by M. A. Curtiss in Florida on the Chattahoochee River; and the same year I traced its distribution through the eastern-gulf states to its western limit.

This Pine, generally known to the people of the country as the Spruce Pine, extends from the coast region of South Carolina just below the line of thirty-three degrees north latitude to the valley of the Pearl River, in Mississippi, to the latitude of thirty degrees thirty seconds, and is in that state as well as in Alabama confined to a belt of from 115 to 125 miles wide. It is found in dense woods with a soil of deep light loam rich in vegetable mould, retentive of moisture, but not wet, and particularly in situations where a more or less sandy subsoil favors a moderate under-drainage. Under the conditions of a mild climate, with an abundant rainfall, and a soil with a fair store of the elements of plant food, the forest-vegetation exhibits in greatest variety and luxuriance.

Here this Pine is found associated with magnificent Magnolias (*M. acuminata* and *M. macrophylla*), the Short-leaved Pine (*Pinus echinata*), the Red Bay (*Persea Carolinensis*), and almost unfailingly the Beech, with its dense foliage of freshest green during the earlier part of the season, standing forth in pleasing contrast with the dark, glistening leaves of the Magnolia and the sombre shades of the Pines. The variety of smaller trees and flowering shrubs adds to the charm and interest of the surroundings of this Pine, amongst them the Holly (*Ilex opaca*), Palmettos, the Farkelberry (*Vaccinium arboreum*), large, bush Huckleberries (*V. virgatum*), the Angelica-tree (*Aralia spinosa*), Red-flowering Buckeyes (*Æsculus Pavia*), Styraxes and Cornels, *Styrax grandiflora* and *Cornus sericea* being most conspicuous. These lands of a rich soil, and supporting such varied vegetation, called hummock lands, are most frequent in the coast region, where the streams emerge from the Pine-uplands to the plain or flat-woods fronting the sea-shore. The Spruce Pine is entirely wanting in the Pine-uplands or Pine-barrens proper, where the Long-leaved Pine forms exclusively the forest-growth. This last reappears again in the region of a mixed growth of coniferous and broad-leaved trees, forming in many parts the upper section of the coast Pine-belt, and extends not further to the northward than the Magnolia, the two trees following almost the same line in the northern limit of their distribution.

In Alabama and Mississippi the Spruce Pine is found singly or in groups of only a few individuals scattered in the localities favorable to its growth. In western Florida, between the Chocta-ha-chee and Chatta-ho-chee Rivers, it forms compact bodies of timber, extending over several acres, and in this region of its best development and greatest frequency its seedlings are found to occupy a prominent place amongst the second growth.

The Spruce Pine attains, on the average, a height between eighty and ninety feet, the tall, finely shaped, but gradually

tapering trunk, from sixteen to twenty-four inches in diameter rising clear of limb for a height of fifty to sixty feet above the ground. In a rich hummock on the Tensas River, in Alabama, rising above the Cypress swamp, a magnificent specimen was observed, rivaling in height the mighty denizens of the lagoon below, considerably over 100 feet in height and fully ten feet in circumference breast high. The bark of the trees of larger size is thick, furrowed lengthwise, somewhat flaky, of reddish brown color, getting closer toward the top, and is perfectly smooth in the crown and limbs, like the bark of the younger trees. The limbs, rising slightly, divide into numerous horizontally spreading branches and branchlets, multiplied by numerous sprouts from adventitious buds, thus imparting to the oval-shaped crown a greater compactness than is found in any other of the Atlantic Pines. The tender shoots of the season are flaccid, as in the Scrub Pine (*P. inops*), and by this peculiarity during the earlier part of the season the tree is readily distinguished from the Short-leaved Pine (*P. echinata*), its frequent associate, which it resembles in foliage, inflorescence and fruit. The leaves of the Spruce Pine are from one and a half to three inches long, and three of them are always found in the short, close sheath; they are more slender than those of the Short-leaved Pine, scarcely half as thick as they are wide, dark green, contorted, and, later in the season, spreading, and are shed during the third year. Densely covering the numerous divisions of the branches, the foliage of this tree is closer than in any of its allied species.

The flowers appear during the later part of March. The lateral short-peduncled cones mature during the second season. They are ovate-oblong in shape, about two inches long and one inch in greatest diameter, and their flexible scales have a flat apophysis and small deciduous prickle, which, in the mature cones, is altogether wanting. This Pine is less urgent in its demands for light and air than most of its congeners. It eschews exposed situations, and it is only under the most favorable conditions, insuring the greatest rapidity of growth during the first stage of its existence, that it is found to prevail in the openings of the forest. It is through all stages of its development of quick and steady growth. Trees felled in Baldwin County, Alabama, showing forty-five and fifty rings of annual growth, measured eighty and eighty-five feet in height and seventeen to nineteen inches in diameter. The rate of increase is greatest during the first ten years, after which it appears to differ but slightly during periods of the same length of time. In one of the trees the space occupied by the first ten rings was found to be two and three-eighths inches wide, by the second ten rings one and seven-eighths, the third one and three-fourths wide, and the fourth one and a half inches wide. The annual rings showed but slight differences in their width. The heart-wood can hardly be distinguished from the sap-wood. Mr. Fillibert Roth, of the University of Michigan, who has given much attention to the investigation of the structure of the wood of our southern Pines, finds the proportion of spring wood to that formed of summer cells in one ring, on the average, as three to two, and in almost every detail the anatomy of the wood of this tree is remarkably similar to that of the Loblolly Pine (*P. Tada*). The wood is light, only slightly resinous, straight-grained, splitting smoothly and satiny when finished, resembling the wood of the Spruce. It is not durable, is wanting in strength and elasticity, and is apt to shrink under exposure to the sun. Hence this rare and ornamental Pine is to be considered of little economic importance as a timber-tree.

Mobile.

Carl Mohr.

Anthracnose or Blight of the Oak.

THE members of the genus *Gliosporium* are upon the increase in this country, so that at the present time there is an anthracnose of many of our plants, some of which are quite injurious to crops. Thus *G. fructigenum* is so destructive upon the fruit of the Apple that it has taken the common name of "bitter rot." *G. venetum* is the anthracnose of the Blackberry and Raspberry, often defoliating the plants infested. *G. ribis* in like manner preys upon the foliage of the Gooseberry and Currant, and *G. Potentillæ* is the anthracnose of the Strawberry-vines. Others still, as *G. lagenarium*, cause the anthracnose or "spot rot" of cucumbers and melons.

With these citations to indicate that the genus is a widespread and destructive one, attention is called to a species of *Gliosporium* that is becoming very conspicuous from its destructive work upon the leaves of the Oak. As early in the season as the last of May, the "burning" and coiling of the leaves upon some White Oak-trees near New Brunswick were so complete that one of two friends during a recent drive called my attention to the "scorched" trees and asked for the

reason, while the other quickly volunteered the supposed explanation that it must have been caused by a fire.

Upon a careful study of the subject it was found that the brown, curled and dead leaves had been attacked by a fungus of the genus *Gliosporium*. In the worse cases the whole leaf was brown, but in many others only a portion had been killed, and of the latter the injured areas were along the main veins in the centre. In other words, the fungus is most active near the centre veins, including the midrib of the leaf, and spore-bearing pustules are usually situated in quite uniform rows, one upon each side of the vein. This is different from any other species of *Gliosporium*, which prefer the soft parts of the leaf and bear the minute blisters or spore patches midway between the portions of the leaf's framework.

This blight upon the Oak proves to be *Gliosporium nervisequum*, and is therefore the same as the one that has proved very destructive to the Sycamore or Button Wood (*Platanus occidentalis*)—in fact, this blight was so violent upon the latter host that it has received consideration in the *Journal of Mycology*. In this it is stated by Miss Southworth that "in some cases trees have been killed outright by the disease and in many the growth of the early part of the year has been completely destroyed. . . . Sometimes the young unglorified stem was attacked at some distance from the end." Also that in early spring "the external leaves of the unfolded buds showed the disease as soon as they were half out and many buds died before they were fairly open." It would seem from this that the blight fungus remains through the winter in the substance of the bud, but possibly only as spores lodged in the folds of the bud, which quickly germinate as the bud begins to unfold in the spring. However this may be, the probabilities are that an Oak-tree once attacked will continue to suffer from year to year and therefore if certain trees show the blight conspicuously it would be wise to mark such for the axe.

This note is written for two purposes: first, to answer the question quite sure to be raised, namely: What is the matter with the "scorched" Oak-trees? and secondly, to point out that the enemy has proved a dangerous one to the Sycamore in many parts of the country, and therefore the affected Oaks, other things being equal, should be the first to fall before the axe, that the further spread of the destructive disease may be checked. It would be interesting to learn how widespread this trouble is the present season.

Byron D. Halsted.

New or Little Known Plants.

Symphoricarpos occidentalis.*

THE North American genus *Symphoricarpos* is well known in gardens, where two of the species are cultivated as often, perhaps, as any of our native shrubs. These are the Snowberry (*S. racemosus*), which is valued for the snow-white berries which cluster along the branches, making a striking appearance in autumn and early winter; and the Coral-berry, or Indian Currant, as it is sometimes called (*S. vulgaris*), which is planted for the small dark red fruit which covers the branches in autumn. The flowers of these two plants, as well as of the other species of the genus, are small and not particularly conspicuous. Four or five species, in addition to the two generally cultivated, are found principally in the western and south-western parts of the United States and in Mexico. Little is known of these plants in gardens, although *S. occidentalis*, of which a figure from a drawing made by Mr. Faxon from the cultivated plant is published on page 297, has been grown for several years in the Arnold Arboretum.

Symphoricarpos occidentalis, like *S. racemosus* and *S. vulgaris*, belongs to Gray's first section, distinguished by the short and urceolate or campanulate corolla, generally less than a quarter of an inch long. It is a slender, graceful shrub, growing to a height of two or three feet, with rather stout terete stems covered with light brown bark. The leaves are oval or oblong, usually pointed and minutely apiculate at the apex, with entire or slightly sinuate margins. They are sometimes two or two and a half inches long and two inches broad, or often smaller, prominently reticulate veined, rather thick and leathery at maturity, and dull green on the upper, and pale on the lower surface,

which is hairy along the mid-rib and primary veins. The axillary flower-clusters are sessile or nearly so, or are sometimes produced on stems an inch or more long, becoming spicate. The pedicels and calyx are minutely puberulous. The corolla is deeply five-cleft, pale rosy pink, densely villous hirsute with long hairs on the inner surface, and rather shorter than the stamens and style. The fruit is a quarter of an inch in diameter and pale greenish white at maturity.

Symphoricarpos occidentalis inhabits rocky, wooded banks from Michigan to the mountains of Colorado and Montana, extending far northward, where it was discovered by Richardson on the Franklin Relief Expedition.

It is the fruit alone which makes *Symphoricarpos* valuable as a garden plant, and as the fruit of this species is less beautiful than the larger and more clearly colored fruit of the Snowberry, it is not probable that it will ever supplant that species in popular estimation. Shrubs, however, which are hardy in this climate, and produce fruit which is showy in the late autumn, are not too abundant, and the Wolfberry, as this species is called in the Floras, makes an interesting addition to the list.

The plants in the Arboretum were raised from seed sent many years ago from Colorado by Mr. T. S. Brandegee. They are perfectly hardy, and receive no special care or cultivation, and produce seed every year. C. S. S.

Plant Note.

Hardy Trees and Shrubs.

THE issue of the *Gardeners' Chronicle* published on the 17th of May was largely devoted to hardy trees and shrubs with showy flowers, the subject of the discussion at the meeting of the Royal Horticultural Society held in London the previous week. It contained a figure of *Prunus Pseudo-Cerasus*, a Japanese tree, much cultivated in Japan, where innumerable double-flowered varieties have been produced. It is a small hardy tree, with clusters of large white flowers flushed with pink. It is sometimes known in gardens as *Prunus Sieboldii*. *Prunus Wateri*, a double pink-flowered variety, is one of the handsomest of the forms of this tree known in our gardens, and certainly one of the most beautiful early spring-flowering trees in cultivation. *Zenobia*, or, as we call it in this country, *Andromeda speciosa*, is also figured. It is the most beautiful plant of its class, and, although rarely seen in American gardens, one of the very best shrubs in cultivation. In spite of the fact that it is a native of the warm coast region from North Carolina southward, it is perfectly hardy as far north as New England. There are figures, too, of *Exochorda grandiflora*, and of *Magnolia stellata*, the dwarf Japanese shrub often found in our gardens under the incorrect name of *Magnolia Hallii*. This last is a very hardy and free-flowering plant, which only needs to be better known to earn the position in popular favor which its great merit deserves. *Berberis stenophylla* is also figured, and so are the European *Amelanchier* and *Olearia Gunniana*. The first is a very pretty hybrid between two South American species—*B. Darwini* and *B. empetrifolia*. It is a plant of neat habit, with small dark green leaves and brilliant golden colored flowers; not always perfectly hardy in the northern part of this country, although it will flower here if the branches are slightly protected during winter. *Olearia Gunniana* is one of the *Compositæ* from Tasmania, with pretty Aster-like white flowers, which are often seen in the early spring in London gardens, but here, like other Antipodean plants, it will not thrive when exposed to the vicissitudes of the climate of eastern America.

Cultural Department.

Raspberries.

RASPBERRY culture has attained such proportions that it is probably foremost among small fruits, both for home and for market use. The improvement in varieties was not defined and satisfactory until we secured the Cuthbert. But earlier sorts were in some respects superior to this standard. The Philadelphia was an enormous bearer and entirely hardy; but its color was a dull purplish red, and its quality, though excellent, not so good as that of several others. The Turner

*I.—Hooker, "Fl. N. Am.," i., 285. Torrey & Gray, "Fl. N. Am.," ii., 4. Gray, "Syn. Fl.," ed. 2, 13.

was sent out by Professor Turner, the enthusiastic Indiana scholar. It was, and is yet, the best early berry; but if not closely cultivated, to prevent suckering, it is worse than useless. It is curious to contrast the superb berries and large crops on a row sharply hoed into hills and a row allowed to have its own way; on the latter you will get next to no fruit at all. I still believe in planting a moderate number of stools of these two sorts. The very best berry I ever tasted as well as finest to the eye, was the Pride of the Hudson, sent out by the late E. P. Roe; but it will not stand well in dry spots and is quite freaky every way. I plant a few yet for home use, but must select a half shaded, moist spot. Mr. Roe quickly refused to sell more of them.

Of purples, the first really good one was New Rochelle; and I advise any one to plant it yet for canning. The berry is not so large as Schaffers, but it is fine in flavor and enormously productive. The bush grows much like the black sorts, and it

Crimson Beauty are to be classed among the failures. Rancocas is not much better.

Of blacks I have very warm commendations yet for Davison's Thornless. This is a very early berry and good in quality. Its size is only medium and its bearing qualities not extraordinary; but it is thornless. I have seedlings from this sort that are some improvement on the parent. I suggest a good deal of effort to get seedlings from this stock until we get really the best. To get rid of the thorns in any branch of the Rose family is a matter of great importance. They are not needed under culture. We have discarded them from our Apples and Pears; we must also have thornless Raspberries.

Souhegan and Tyler are nearly alike and truly admirable. Gregg for late was a noble berry, but too tender. At present I plant, besides Davison, Palmer for early, Hilborn and Ada for later. I have very high expectations of Palmer, but have not much personal experience with it.

Fig. 42.—*Symphoricarpos occidentalis*.—See page 296.

roots at the tip. Schaffers kills back somewhat, but I always get good crops of large fruit. Where it does well it is a magnificent acquisition. These two purples far surpass the reds for canning, giving a superior flavor and more body.

Of the yellow varieties nothing was better than Brinkles Orange until Caroline was sent out. I am not so highly pleased with Golden Queen as some have expressed themselves; but it is a fine berry. For a near market the first is the best. It has no keeping quality. The value of yellow berries is mainly to secure something handsome by way of contrast with the red ones. For market, it is well to have one crate of yellow to ten of the reds and one or two of the purples.

We may wisely, I think, hold Cuthbert to be the main-stock red berry, adding Turner for early; for yellows planting mostly Golden Queen; and for purples New Rochelle and Schaffers. I have several other sorts on trial that may prove of high value. Marlboro is not a berry of high quality, but it may be advisable to plant it for early. Hansell and

For a small home garden select Turner and Cuthbert, Golden Queen, Schaffer, Davison and Palmer, and Hilborn.

The matter of culture is most important. Plant in the rows as close as you can; but keep your rows more than wide enough to cultivate with a horse. Set stakes every twenty feet and run one wire about four feet high. Tie the canes in bunches of two to four to the wires, with coarse hop twine. Tie tightly. Cut the canes back to six or seven feet. With wires you can grow them to that height safely and profitably. It is not an expensive plan, and the result is enormous crops. The high culture also prevents the need of cultivating the soil except in early spring.

Mulching is always good for everything, from Strawberries to Apple-trees; but the Raspberry likes a cool soil and an even temperature. The secret of success is mulching and wiring. But high culture so shades the soil as to prevent drying in ordinary seasons. The best mulch is sawdust.

I have a plan for growing red Raspberries in stools between

my Currant-bushes.' Set rows of Currants and Raspberries alternate with Grapes and Strawberries. The Strawberries do not injure the Grapes and give a fair crop. The Raspberries do not injure the Currants if not grown too thickly. It is always easy with the hoe to keep red Raspberries within reasonable bounds.

The increased acreage of berries does not any more than keep up with the increase of demand; and it will not. About one-half of the experiments made are very temporary, as berry culture to be profitable must be clean. *E. P. Powell.*
Clinton, N. Y.

Notes on Trees and Shrubs.

THE Laburnums in the vicinity of Boston have been unusually laden with their bright yellow blossoms this season, even very small plants bearing flowers in profusion. The Laburnum is not quite hardy enough to give general satisfaction in this climate, and, to succeed at all, it requires a somewhat sheltered situation, and more particularly a dry, well drained soil—a poor soil on a dry bank being preferable to a rich and moist one where growth would be rank and continued late in the season. Another trouble with these plants in this latitude lies in the fact that the bark of the main stems is sometimes liable to become destroyed or blighted in winter if the plants are in a position where the direct heat of the sun strikes upon them. Similar injuries are not uncommonly produced in some tender varieties of Pear and other fruit-trees as well as some other of simply ornamental value. Consequently, it is noticeable that the Laburnums which do best are those on the north side of a group of other trees, or even partly under their shade, so that the stems are not subjected to sudden thawings from the direct rays of the sun in midwinter. Since the Laburnum is commonly used in Europe as a standard stock upon which to graft *Cytisus purpureus* and other allied hardy ornamental species, and these grafted plants are sometimes imported into our northern gardens, care should be given to provide some shade in winter for the tall, bare stems.

In striking contrast to the floriferous aspect of the Laburnums is the barrenness of the Yellow-Wood-trees (*Cladrastis lutea*) this season. In all sorts of situations, as under high cultivation or growing on lawns, these trees are entirely without flowers. This species usually blooms regularly every year, and its behavior this season is unaccountable, because the last year's growth was vigorous and healthy and was not injured in the slightest degree during the past winter. The Locusts, however, are as full of bloom as usual. The hardiness of the Yellow-Wood and its hitherto general freedom from insect attacks and other diseases, seem to make it worth testing as a stock upon which to graft other species and varieties of the Pea family. In this country, when the Locust is used as a stock, the stems are often rendered almost worthless in a short time by the attacks of boring larvæ of several species of insects.

The Chinese *Deutzia parviflora*, of which an illustration appeared in the first volume of GARDEN AND FOREST (p. 365), has flowered as profusely as usual this season, and seems to be quite as hardy as *D. scabra* or *D. Sieboldiana* when growing under the same conditions. The tips of the branches are sometimes destroyed in winter, but the injury is rarely so severe as to seriously affect the blossoming. The flowers appear somewhat earlier than those of the hardy, common *D. gracilis*, and they fade away before the last species has passed its period of greatest beauty. The flowers of *D. parviflora* are very different in appearance from those of any other *Deutzia* in cultivation, although they may not surpass some of them in beauty and interest. While they would properly be described as white, the flowers of this species, when compared with those of *D. gracilis*, have not the pure snowy whiteness of the latter, but are slightly tinged creamy white, in some cases as deeply as the blossoms of *Philadelphus coronarius*, the most common "Syringa" or Mock Orange of our gardens. The flowers are prettily arranged in large corymbs, and they are as interesting when closely examined as when seen at a distance on the plants. They are of very uniform size on any plant, but on different plants they vary from a little over a third to over half an inch across. They are flat, with rounded petals, in general appearance resembling small Hawthorn blossoms more than any other familiar object. The fragrance, also, is strongly suggestive of the Hawthorn, though not so intense. *D. parviflora* is a stiff, upright growing plant, which attains a height of six or eight feet about Boston; and the flower-bearing branchlets are also rigidly erect and not flexuous. This species appears to be very rare in cultivation, but is likely to be much advertised in the near

future. The variations noticeable in the size and color of the flowers of seedling plants indicate that the species is capable of much improvement by selection and cultivation. Seed is produced on the plants here, and any peculiar form which may arise can be easily propagated by cuttings of ripe wood taken in the autumn or winter, or by green cuttings from the plants in June and July.

Arnold Arboretum.

J. G. Jack.

Notes on American Plants.

Brodiaea multiflora, from the Pacific coast, bears a close, round umbel of sessile, bluish purple flowers half an inch wide. But they are so close together that they have a different appearance from most of the *Brodiaeas*. The long naked stems grow about twenty inches high from a bulbous root, and the leaf is long and grass-like. It is a strong-growing species, but should be protected in winter.

Iris longipetala, from Oregon, blooms about the same time as our common *I. versicolor*. Its leaf is long and narrow, and the stem, usually two-flowered, is almost naked, a foot or more high. The flower is a trifle smaller and paler than that of *I. versicolor*, but a casual observer might think it the same if he did not compare the leaves of the two. It needs at least two years to become thoroughly established, and then it makes a pretty plant. The flowers are useful for bouquets.

Lilium parvum and *L. Columbianum* are both from the Pacific coast, and come into flower about the same time with the first of the Lilies. The former is a California plant, while the latter comes from the vicinity of the Columbia River, in Oregon and Washington. Both have reddish yellow flowers, with dark red spots in the centre, but the divisions of the flower turn back in *L. Columbianum*, which gives the flowers a different appearance. *L. parvum* seems to thrive best in a light loamy soil, while *L. Columbianum* needs a heavier clay loam or a mixture of clay. The leaf of the latter seems to dry up and die even before it is in bloom when set in a light soil. Both species have small flowers, but they are a little more numerous in *L. Columbianum*, and the plant is a third taller than the other.

Vancouveria hexandra is now in flower, and is a charming little plant. Its delicate dark green foliage, which in color and appearance somewhat resembles that of *Thalictrum anemonoides*, would alone make it worth growing. But the small waxen-white flowers, on long stems in a loose raceme, are delicate and pretty, peculiar in shape and valuable for cutting. It needs time to become established, but it soon spreads from underground stems and forms dense beds. It does fairly well in the open sun, but our plants that are placed in a thin shade do the best.

Allium falcatum, from Oregon, grows only four inches high, but its umbel of dark rose-purple flowers is very large for its height. The flowers are about half an inch wide. The divisions of the flower are very narrow, which gives it an odd appearance. Its very short stems make it worthless for cutting, but it is an interesting garden plant, remaining a long time in flower. It is probably not hardy.

Mimulus Lewisii, another native of Oregon, a foot or more high, has numerous crimson flowers, an inch long and nearly as wide at the mouth of the flower, very showy and durable. Open sunlight and a light soil seem to suit it.

Southwick, Mass.

F. H. Horsford.

Hardy Flowers in June.

APRIL and May are the brightest months in the rock garden, when Moss Pinks (*Phlox subulata*) in variety, Aubrietias, Arabis and Hepaticas are at their best. June is the brightest for the borders. Columbines are among the earliest and most beautiful, I think, of all border plants; and the handsomest of these is the Siberian species, *Aquilegia glandulosa*. It is quoted at high prices by dealers, but it is very easy to raise. There is some question as to the probability of obtaining the species true; but there should be little danger of its becoming hybridized, as it is nearly past blooming when the other species come in, with the exception of *A. Canadensis*, which does not seem to affect it. My plants from seed saved by myself are perfectly true. One-year-old seedlings bloom better than the best imported plants. This may be accounted for partly by the fact that all Columbines are impatient of removal. In our case they suffer very little from it, being removed from the nursery directly into the border.

The hybrids between *A. cœrulea* and *A. chrysantha* are beautiful, having the graceful curving spurs so well developed in *Chrysantha*. The blue and yellow varying in lighter and deeper shades harmonize splendidly. The "Munstead

Giant," a white variety of *A. vulgaris*, is a very attractive border plant, and being of robust constitution is not so likely to die out as some of the more delicate kinds. Another bold kind is *A. Olympica*, with flowers of a lovely violet-blue.

Moutan Pæonies and German Iris, and later, herbaceous Pæonies follow. Any one wanting a gorgeous effect lasting through June can have nothing better than these with Sweet Williams mixed in. *Pæonia tenuifolia*, single and double, are striking and distinct, and very early. All the single varieties are handsome. They are easily obtained by sowing seed saved from the ordinary double varieties, about half of which come single or semi-double from seed. A friend tells me germination is assisted by soaking the seeds two weeks before sowing.

After these come Foxgloves. They are strikingly beautiful. We formerly protected them during the winter, but this season

Novelties in Hardy Plants.

THE new Carnation, Paul Engelheart, is without question the best border Carnation of the Clove section yet introduced. The color is the same as in the old Crimson Clove, but the flowers are almost twice the size, and, if possible, more fragrant than those of that good old garden plant. The great advantage claimed for Paul Engelheart is that the stems are stout and well able to support the large flowers, and this is so even when cultivated under glass. I am not positive that this Carnation is thoroughly hardy, but there is every reason to believe it will prove to be as hardy as all others of its class—that is, with a little dry litter placed round the plants in fall. With this treatment the Scotch Pinks generally winter nicely even in exposed situations, and furnish an abundance of beautiful, fragrant flowers in June.

Parterres in the Park of Saint Germain.—See page 294.

they have taken care of themselves in the shrubbery border, where they appear to be at home. The yellow-flowered species, *Digitalis ambigua*, is a distinct and attractive plant, and seems to be hardier than *D. purpurea*, the common kind.

The month finishes with Sweet Williams and Delphiniums at their best. Selection does considerable with these perennial Larkspurs. We have now some very fine double ones. I saved seeds from a lovely sky-blue flowered variety named Belladonna, which I am told never produces seed, and if so my plant must have been wrongly named, though trusting to memory I should say it was true enough. By hybridizing this with the old *D. formosum* I have some very fine distinct kinds and a few very double ones. No other plants furnish so wide a range of blue, from the palest to the most intense, as do these perennial Larkspurs. If they are cut back as the flowers fade, another crop of bloom will appear, so that they will brighten the border until autumn.

Wellesley, Mass.

T. D. H.

Of the two scarlet Delphiniums, *D. cardinale* and *D. nudicaule*, the latter is the best plant, being a better perennial than the former, but both are desirable owing to the quality of flowers they produce, the brilliance of their scarlet color, a color by no means common among hardy perennials, and the neat dwarf habit of the plants and their branching habit, which make them desirable for the front rows of flower-borders. Among recent novelties is an orange-colored variety of *D. nudicaule*, called *Aurantiacum*. This is fully as good a plant as the type, and differs from it only in the color of the flowers, which are of the brightest orange. These scarlet Larkspurs are often accused of being tender and only biennial in duration, but it is easy to raise them from seed, for the seeds germinate as readily as those of the old *D. Chinensis*, and it is surprising what an amount of satisfaction one derives from the fact of doing a plant well when it has a reputation for being hard to grow, especially when the subjects have a special beauty of their own as is the case with these scarlet Larkspurs.

I took occasion in a late number to advocate the cultivation of *Alstromerias*. Since those notes were written it has been our good fortune to flower the gem of the family *Alstromeria pelegriana alba*, the Lily of the Incas. This plant is far too rare in gardens even in the old world, and the only reason there can be for its not becoming more common is that so few have an idea of its exquisite beauty. In stature this species does not exceed eighteen inches, and the flowers are pure white, with a few spots of green in the throat, giving it a chaste beauty only to be compared to that of an Orchid. There is reason to believe that the Lily of the Incas will prove tender in the colder states, and it certainly would be unwise to risk a unique plant the first season, as it might be easily and safely wintered in a cool cellar and replanted in spring. The raising of *Alstromerias* from seed is easy, provided fresh seed can be obtained. Old seed often takes two years to germinate, and the seeds should be sown and kept under glass, since the plants are peculiar to South America. Our plants were received in the fall and were potted and kept dry until signs of growth were visible, when water was sparingly applied until spring, when flower buds were produced, and in May there were many umbels of the beautiful white flowers expanded, the plants promising to flower all summer, this being the way all the other species have behaved that we have tried.

Reading, Mass.

E. O. Orpet.

Odontoglossum maculatum.—During March, April and May one may begin to look among the *Odontoglossums* for the flower-spikes of this attractive species, although I have seen plants in flower in December and January also. The pseudobulbs are ovoid, much compressed, each furnished on the summit with a broad, grassy green leaf six to nine inches long, and distinctly veined longitudinally. The flowers, which vary in size, are usually two to three inches across, and are borne on pedicels about four inches long, clasped at the base by a large pale brown bract. The sepals are lanceolate-acute, sharply keeled behind, with a corresponding depression in front, the color of which is a very dark brown, with a few obscure pale green transverse markings at the base. In comparison, the petals are broader and shorter, oblong-ovate acute, suddenly narrowed at the base, and of a clear yellow color, heavily blotched on the lower half with dark brown. The lip is cordate-acute, with a jagged margin; it is yellow, like the petals, and covered with deep brown blotches, which stand out in bold relief against the ground color. The callus, or crest, is of a deeper yellow, with brown lines at the sides, and is something like that of *O. Rossii*, but has a central ridge dividing into two horns in front.

O. maculatum was discovered many years ago by La Llave & Lexarza in Mexico in the neighborhood of the Irapean Mountains, near Valladolid, but its first appearance in cultivation was due to Mr. Barker, of Birmingham, in whose collection it flowered for the first time about the year 1845. It has been largely imported since that time, and is now one of the best known *Odontoglossums*. A closely allied species is *O. cordatum*, also a Mexican plant, with which, in years gone by, *O. maculatum* was confused. *O. cordatum* may, however, be readily distinguished by its longer, narrower and more acuminate sepals, petals and lip, shorter pedicels and looser habit.

Pot cultivation seems to be the most suitable for *O. maculatum*, and a temperature varying from sixty to sixty-five degrees Fahr. in winter to seventy to seventy-five in summer. During growth water may be freely given, as well as enough air to enable the growths to ripen properly. The pots, of course, must be well drained with clean crocks, and the soil should be the usual compost of fibrous peat and sphagnum, in about equal proportions.

Salvia Splendens, *Ingénieur Clavenad*, is in bloom from seed planted in January. This variety was first offered this season, and, as will be seen, is rather earlier and blooms in a smaller state than the type, and the cluster of flowers is, perhaps, larger. The color is a bright scarlet, and it will probably prove valuable for early flowers.

Delphinium Nudicaule, var. *Auriantiacum*, is a new variety, probably not yet much distributed. Its habit is like the type, dwarf and compact; probably it will prove equally unreliable as a garden-flower. The flowers are small, of a pleasing reddish orange shade, and numerous. A very distinct plant for a collection, but very inconspicuous in comparison with the numerous very beautiful hybrids now in cultivation, than which there are few more pleasing and satisfactory plants for a large border.

Dianthus plumarius *hyb.*—There seems to have been little attention paid to this cross between *D. plumarius* and *Carna-*

tion remontant, made by M. Alegataire, of Lyons, a few years since. As the plants in their second year, in a bad spot in the border, prove to have a very sound constitution, it seems well to call attention to the hybrid, as some skillful cultivator may find it well to take it in hand and improve the flowers, which at present are single or semi-double and rather dull colored, though fragrant. It is a free grower with long stems, with a great flush of bloom in June and scattering flowers during the summer.

Elizabeth, N. J.

G.

Abutilons.—In connection with Dr. Masters' interesting article on "Sports" may be mentioned the peculiar action of stock on cion in the case of *Abutilons*. On a well-variegated form of *A. Thompsoni* were budded four varieties with green leaves. A yellow-flowered one took the variegation completely, and cuttings have retained it for two years. A strong variety with large, bell-shaped, red and orange-veined flowers took the variegation at first, and afterward lost it. One variety with pink flowers and cordate leaves showed no markings on the leaves; and the other with spreading, orange-striped flowers showed less than the stock, but was still decidedly variegated. The variegated form of *A. megapotamicum* will turn green on a green stock, and will show variegation on stock of variegated kinds.

Correspondence.

Gardens for Hardy Plants.

To the Editor of GARDEN AND FOREST:

Sir.—The interesting editorial on the Spring Garden in your issue of May 7th suggests a few thoughts on the cultivation of hardy plants in small gardens, where they are too often entirely lacking or represented possibly by a stray Phlox, Iris, Peony, or other strong growing plant, whose growth is so apparent in the early spring that it passes safely through the annual tidying up. During May one will observe that the average small garden, so-called, is an expanse of bare earth nicely raked over and waiting for warmth and the plunging of such tender plants as have survived in-door culture. One notices these plants later in various stages of surprised discouragement at the sudden change to fresh air and their slow progress to health and vigor. Where new plants are purchased annually it is a little better, but even then a good part of the growing season is over before the garden is fairly filled with foliage and flowers. Without intending any depreciation of tender and bedding plants, be they ever so common or commonplace, it does seem that one who is fond of a garden or enjoys country life misses much if he pursues year after year the old routine with such plants for the very short season from the middle of May to early October, when by a judicious selection the garden may be made a pleasure from April 1st to late November; and even longer in some seasons like the present, where flowers have not been wanting in some gardens since early January. By all means retain the old favorites; but why not secure a selection of long-lived plants which will invest the garden with an increasing charm every year, and then with the addition of a few good annuals the garden can be made interesting always, and to furnish great quantities of flowers for a long season. To get a garden of this character into a satisfactory condition requires study and time, and unless one has an inherent fondness for the work and some patience, it is not advisable to begin without the aid of a skilled gardener. But assuming that no such assistance is practicable, how shall one entirely unfamiliar with hardy plants who finds himself in possession of a small garden proceed to collect and grow hardy plants satisfactorily? This is too large a question for a brief reply. Perhaps a few notes from the standpoint of an amateur who has found in a small garden a pleasant relaxation during the few leisure hours of a busy life may be helpful.

The proper time to start such a garden is now, or any time when the borders may be dug. Do not be over ambitious at first or make such elaborate plans that discouragement will follow a lack of immediate success, but have a space or spaces in different parts of the garden deeply dug and loosened and add a fair amount of manure after taking care that the drainage is perfect, for the hardy-plant border, as a whole, should never again be disturbed. The more or less unreliable laboring men (not to dignify them by the name of gardeners), whom cultivators of small places are forced to employ, have so long annually upset every available bit of ground and ruined all perennial roots that it seems to have become a tradition that such a course is the only proper one. A slight

consideration will show that such a practice destroys all hope of satisfactory effects. If the border is well drained and well filled with plants and their roots, any deep disturbance of the ground must work some injury to them. The only possible excuse for disturbance would be that the soil might become sour if not stirred, but it will not grow sour if drained and full of growing roots, as a slight inspection of any bit of wild land will prove. Then this upsetting in the spring disturbs the seeds which naturally fall in the borders, many of which will germinate and prove useful in furnishing new plants for the border or for friends. One is also apt to have some favorite hardy annuals in the border, and one of the pleasures of spring is the annual appearance of these old friends from self-sown seeds, which usually produce strong, healthy plants. Advantage may be taken of the shifting or division of plants to lighten up the soil, and at convenient times during summer manure may be spread on the border if necessary to keep ground in good heart. It is also a good plan when dibbling out seedlings after watering to give them a slight mulch of well rotted manure, which saves much attention, helps to keep them clean and gives them a good start. An excellent position for a hardy border, and one often available in a small garden, is on the north side of a picket fence. In summer this shades the plants slightly, if at all, and during winter and early spring, when sun is low, shades them enough to prevent constant thawing and freezing, which is so fatal to many plants.

One who devotes himself to hardy perennials is necessarily forehanded, as plants are not to be had fully grown and in flower, and planting must anticipate flowering for some months usually. Where taste differs so much it is hard to advise as to the selection of plants, but probably the satisfactory plan for most novices would be to concentrate their efforts and select the more showy and free-growing plants, not trying for a general assortment, but for a fair number of certain families, so that during the season successive displays could be secured—accentuating the season, as it were—in different parts of the garden. Such selections, to name only common plants of a showy character in about the order of their blooming, would be Primulas, Daffodils, Dutch bulbs (Tulips, etc.), Columbines, Irises, Peonies, Poppies, Pyrethrums, Larkspurs, Hollyhocks, Sunflowers, Perennial Asters and Chrysanthemums. This list is a very short one, yet, if one were so disposed, he could find interesting occupation in collecting plants of only one of the families named. A small garden would scarcely contain specimens of all the various Irises, for example, numbering up to the hundreds, which may be had; and so with Primulas and others. Collecting, however, is one of the refinements of gardening which may be deferred until experience is gained. For a beginner it might prove more expensive than satisfactory. At first, it is well to acquire some knowledge of the various families and buy only plants which are likely to suit one's special taste, bearing in mind always that nurserymen's prices are no indication of the beauty of their flowers, except that for a beginner the cheapest are usually the very best, having been in cultivation a long while and found worth growing in quantity. One is apt to find, on growing a new plant, that the insect specially fond of it will quickly appear to claim his tribute, so the fancier whose taste is turned toward one family of plants finds that some enterprising florist manages every season to furnish a few new things exactly in that line, and he is assessed for an unending tribute. However, as man is a collecting animal, this is a very pleasant feature of gardening, and with as much of the excitement and as few annoyances as any of the usual fads. Many unkind things are said of the nurserymen, very unjustly, in connection with their offering of new plants, but usually by buyers entirely ignorant of flowers. No doubt, there are dishonest dealers who coolly advertise plants as belonging to a genus with which they are not even remotely connected, but it is usually the buyer's fault if he is deceived. One soon learns to neglect plants which will not please one's special taste, and yet almost any plant will prove of interest if it belongs to a family of which a collection is being made.

The heart of any garden is the seed frame, for from seeds one may raise most plants desired in quantity and it is an un-failing pleasure to watch them in all stages. The frame should occupy a sheltered spot and be covered with glass in winter and "shading" or slats in summer, and attention should be given to watering when necessary. In such a frame seed can be sown at any time it can be secured. Many seeds of hardy plants will germinate at once, some not for months, some only after warmth and some after freezing; so do not be in a hurry to disturb the seed-bed if plants do not soon appear. As to culture, one of the first discoveries the novice makes in a garden is that plants usually grow well—if you let

them. In good soil none of the popular plants are likely to prove difficult subjects to grow and one soon learns to note quickly any lack of vigor or health by the appearance of the foliage, which some simple remedy will set right. It is probably agreed that gardening is an empirical art and with our present knowledge of plant structure it is almost impossible to say without experiment under what conditions most plants will not live and thrive to a certain extent. Like man, certain of them have an adaptability to changed surroundings, though there seems no general rule for this. The Flag Iris of our swamps is usually found with its feet in water, yet it is an excellent plant for a dry border; remove a Lily pad from its floating home and the first sun shrivels it. Perhaps the best cultural directions can be found in such works as Canon Hole's "Book about Roses," in G. H. Ellwanger's "The Garden's Story," John Burrough's sketches, Alphonse Karr's "A Tour Round My Garden," and other books which inspire a love of nature and present pleasing pictures which one would wish to develop in a garden.

One should try to have his grounds filled with plants, leaving them as far as possible to their natural habits, crowded artfully that they do not smother each other, avoiding stiff, formal arrangements and leaving the culture of specimen plants to professionals, for the ultimate pleasure of the work is the cutting and distribution of the flowers and plants. Consider no flower too rare for a friend, and always let a liberal supply of stems and foliage accompany the gift—it is better to spoil a plant than a bouquet, in which one's reputation for taste is at stake.

Every owner of a garden should bear in mind those words from Alphonse Karr, "I do my utmost to spread and render common and vulgar all the plants and trees that I prefer; it is as if I multiplied the pleasure and the charms of beholding them of all who, like me, really love flowers for their splendor, their grace, and their perfume."

Elizabeth, N. J.

Orchids in Flower at Wellesley, Massachusetts.

To the Editor of GARDEN AND FOREST:

Sir.—In the large conservatory connected with H. H. Hunnewell's residence at Wellesley, a fine display of Orchids in full bloom has recently been arranged in a very effective way. Just now the Cattleyas form the prominent feature, and many of the plants are remarkable for vigor and abundance of bloom. Among them I lately saw at least twenty-five examples of the beautiful *C. gigas*, many carrying several spikes each, and the blossoms were noteworthy for their size and coloring. A plant of the true variety, *Sanderiana*, measured nine and a half inches across, the sepals and petals being broad, the lip intensely rich, and the two eye-like blotches on either side of the brightest golden yellow. *Cattleya Mossiae* was also well represented; in some varieties I observed the purple coloring in the lip of the large flowers almost absent, and replaced by a blotch of rich yellow. *C. Mendelii* here had produced some fine varieties with round, well-shaped flowers, the broad-fringed lips being invariably very dark. *C. Gaskelliana*, too, with its showy and fragrant blossoms, was flowering very abundantly. Among this group of plants were scattered several distinct varieties of *Lalia purpurata*, all large, well grown plants, and a fine example of the variety *Alba* carried several large, broad-petaled blossoms.

The rare *L. grandis*, with its buff-yellow sepals and petals and finely marked lip, was represented by a plant carrying three good-sized flowers. These were arranged together with a group of well-flowered *Odontoglossum vexillarium*. The plants were clean, strong and healthy, and were carrying six to eight flowers on a stem, and showing decided variations in color, from warm purple to a delicate white. A plant of the scarce variety *Cobbianum*, with flowers almost white, was very attractive. Some fine examples of the pretty *Oncidium Weltonii* had strong, well-branched spikes laden with quantities of bright olive-brown and purple flowers. The white and purple flowering *Odontoglossum cirrhosum* produced a charming effect, arranged with their long stems hanging gracefully among the flowers of the Cattleyas. Many *Dendrobiums*, too, were flowering freely. At least a dozen plants of *D. thyrsiflorum* were carrying three or four spikes each, and one specimen showed nine well developed clusters of its white and orange flowers. *D. Devonianum* hung from the roof, with a mass of flowers, on bulbs measuring three feet in length. A plant of Woolley's variety of *Sobralia macrantha* gave added interest to the group just named, its rich color blending harmoniously with that of the other flowers. Many examples of the beautiful *Odontoglossum crispum*, *O. Pescatorei* and *O.*

citrosimum added to the display, with fine specimens of *Cypripedium grande*, *C. caudatum*, *C. barbatum* and its variety, *C. Warrentii*, *C. Haynaldianum*, *C. Veitchii* and other excellent plants. A. Dimmock.

The American Association of Nurserymen.

Fifteenth Annual Meeting—II.

ABSTRACTS of a few more of the papers read at the Convention of Nurserymen in this city are given below. It is a matter of regret that our limits as to space will not permit us to quote them more fully.

THE RELATION OF NURSERYMEN TO THE FORESTRY PROBLEM.

The general ideas involved in the forestry problem are well known. There are two phases of it—the one which is concerned with bringing about a more rational management of our existing natural forests; the other, which contemplates the need of creating artificial forests.

With the first part of the problem—the application of forestry or forest-management to the virgin woodlands—the nurseryman has a connection only in so far as he, like every other citizen, should take an interest in a rational development of the resources of our country. Of this interest it needs only to be stated that the forest-property, which we hold in common, the so-called Government timber-lands, are annually decimated by fire and theft at the rate of from \$10,000,000 to \$20,000,000 worth, for lack of proper administration; that under present methods of lumbering not only are forest-supplies squandered in an unintelligent manner, but the natural reforestation which would, under rational methods, take place, is, on large areas, made precarious or impossible; that the White Pine of the north is fast disappearing without reforesting itself to any extent; that several specially valuable timbers, like the Walnut and the Ash, are growing scarcer every year; that, by the denudation of slopes, by removing the forest and burning off the forest-floor, in many sections the soil is washed away, the water-flow is made uncertain, giving rise to excessive local floods and low water. In short, the lack of a rational forest-policy is apparent on every hand, and, as citizens, nurserymen ought to take an interest in changing the state of affairs.

In one way the nurseryman can exert by his knowledge and through his connection with arboriculture a special influence. One of the means employed by the forestry reformers to pave the way for a better forest-policy is the establishment of Arbor Days in all the states; now thirty-six states have such Arbor Days; we are ripe for a National Arbor Day. The idea of Arbor Day is not so much to increase the tree-growth of the country as to create, especially among the younger generation, a spirit of conservatism in opposition to the destructive spirit of the wood-chopper, a love for trees and a knowledge of their value. The nurseryman, with his knowledge of tree-growth, can aid and advance this reform work considerably by his advice. He can do more. He can assist by being present at the Arbor Day celebrations and show the ignorant how to handle a tree. He can do still more, if he is generously inclined, like Mr. George C. Roeding, of Fresno County, California, who furnishes this year on Arbor Day to every school district in his county, free of charge, two Maples, one Texas Umbrella-tree, two Fig-trees, one Pear-tree, one Locust-tree, two Olive-trees, one Fan Palm and two Rose-bushes. This is well directed generosity, and it is only necessary to promulgate the idea to have it generally appreciated by other generous nurserymen.

A more intimate relation of the nurseryman exists to the second part of the forestry question, the creation of new forests. Here his business interest comes into play more directly, and he becomes a more important factor in the forestry problem. In the old countries forestry began with the management of the natural woods, and when it became necessary to recuperate these by artificial planting or to create new forests, the forester grew his own material and planted it himself according to his knowledge of forest-conditions. It is questionable whether of the four to five million dollars which Germany spends annually for artificial planting an appreciable amount goes to nurserymen for plant-material, most of which is grown by the foresters themselves. Lately, however, some few large nurseries make quite a trade in supplying forest-tree seedlings and seeds.

In the United States this is quite different. Forests under management do not exist; forestry as a profession and foresters do not exist as yet, and the nurseryman not only furnishes the plant-material, but gives advice or even does the planting himself under contract. Upon him rests largely the

responsibility whether this phase of the forestry problem shall be successfully solved, or whether its forest-planting become soon a well established practice, wherever needed, or whether its solution shall be kept back and failures be more frequent than successes.

There is no need of discussing the question, whether, so far, nurserymen have discharged this responsibility successfully; whether, considering the novelty of conditions, absence of experience and the many other difficulties attending this, to them, new departure in arboriculture, they have done the best they could; nor is this the occasion to inquire to what extent forest-planting is practiced or to criticise defective measures or even to propose new methods. Every one who is familiar with the subject knows that, greatly as the practice of planting to forest has increased of late, a much greater increase is necessary to make a visible impression upon the treeless plains of the west, and still more so to recuperate the waste lands in the east, and to fill the gap made by the lumbermen in the north. Such enterprising men as Robert Douglas, Thomas Meehan and your first Vice-President, Mr. C. J. Carpenter, deserve public gratitude for what they have already done, and, no doubt, others are prepared to do as much; and yet it may be worth while to outline a few points for every nurseryman to consider when he contemplates any efforts in the line of forestry.

In the first place, he should recognize that forest-planting has a different object in view from the planting for which nurserymen have been and are most of them now accustomed to supply trees.

In the latter case it is beautiful form, shady or brilliant foliage, and, above all, it is the single tree he has to deal with. In forest-planting the ultimate object is timber and continued protection against climatic ills. Here he deals with masses, not with individuals. With the change of object, a change of method necessarily follows. What is right and proper in the selection of material and its disposition by the landscape-gardner, is not proper for the forest-planter.

The nurseryman, then, who undertakes to advise on forestry matters, cannot do so purely from his knowledge of the behavior of trees in open grounds and along road-sides, but he must have studied their behavior in the forest; he must have studied, at least, the principles of forestry; he must know by what means forestry, as a science, utilizes the behavior of different trees in combination, so as to produce desirable forest-growths and forest-effects in the cheapest manner and in the shortest time, imitating nature and yet improving upon her from the economical point of view. One of the principles which is well developed and established by the experience of European foresters is little understood among our forest-planters. This is the superiority not only of dense planting, but of mixed planting and grouping over the method of planting one species by itself. Yet it is not so much variety and promiscuity that is desired as some seem to think; there are much more rational objects to be served by such mixing and grouping. There must be a reason for the choice of a combination and a system in the arrangement, which is conscious of its object. Favorable forest-conditions are to be established as the first aim of the forest-planter, and these, as we find them in the best natural forest, consist in dense growth, mixed growth, undergrowth. By so much as any of these conditions is deficient or lacking, by so much is the forest short of the ideal.

In the selection of the species to be grouped, besides the capabilities of the same to thrive in this locality and soil-conditions and to yield the most desirable wood material, three points must guide the planter: (1) Their relative capacity for preserving and increasing favorable soil-conditions; (2) Their relative dependence for development on light and shade; (3) Their relative rate of height-growth. Without tracing at length the meaning of these points in particular, it may be stated as a consequence of their consideration that there are five principal rules to be kept in view in making selections for grouping:

I. The main growth, i. e., the one that occupies the larger part of the ground, must be of a kind that improves soil-conditions, namely, a densely foliated, shade-enduring kind, which does not lose its shading capacity with age.

II. Shade-enduring (i. e., densely foliated) kinds may be grouped together, if the slower grower will endure the shade of the rapid grower, or can be protected against its supremacy by being planted in larger specimens or in advance of the former, or in larger numbers; or if its gradual killing out after it has served its function of soil cover is not objected to.

III. Light-needing, i. e., thinly foliated kinds, should never be grouped together where soil-humidity is to be preserved, unless no shady tree can be found to fit the locality.

IV. In grouping light-needing with shade-enduring kinds, the former must be the more rapid growers or must otherwise be given an advantage.

V. The mixing in of the light-foliaged trees is preferable, done in single individuals and not in groups, unless special soil-conditions necessitate the latter method.

The last, and perhaps the most vital relation of the nurseryman to the forestry problem after his generous tendencies and communal interest have been touched, is one that touches his money interest.

The nurseryman furnishes the plant-material to the would-be forest-planter. What grave consequences does this have upon the success of the plantation! If honest service is of utmost importance to the producer of an annual crop, how much more must it be with a crop which matures only after many years! All the arguments for pure seed, fresh seed and seed true to name apply, of course, to the furnisher of forest-tree seeds and of plants as well, and more. The man who sells seedlings pulled from the forest for nursery-stock stands on the same plane with the man who sells oleomargarine for butter, or with any other fraud.

Buyers of ornamental stock spend their surplus for their pleasure; whether they pay a little more or a little less is in the end of not much consequence to them; they can readily allow an extra profit, since they themselves thereby suffer but little. The man who buys stock for forest-planting does so because of necessity, if he be on the naked prairie, or for profit. He cannot afford to pay more than the reasonable profit for what he buys.

Forestry, especially, which yields returns only after many years of investment, cannot afford to carry high initial expenditures on which to pay interest. The profitableness of forestry, any how, is a matter over which enthusiasts are apt to rave, judging from the results of some isolated and favorably conditioned cases, but which, when taken at large, cannot be so readily proved. Like any other legitimate business of a general nature, which is not capable of monopoly, it requires close calculation to make it a financial success. In a contract of a Nebraska nurseryman, who makes a practice of planting timber claims, the amount paid out for plant-material is forty per cent. of total cost of planting. (In Germany the plant-material costs thirty-four to forty-six per cent. of total cost.) It becomes, then, of considerable consequence whether good plant-material can be had at reasonable prices.

It is not easy to determine at what advance over the cost of production an article may be sold to make profitable business; so much depends upon the size of the business. A druggist must take from 100 to 500 per cent., while a steel mill may make money with a four per cent. margin. Nor is it easy to determine how far abundant and cheap supply will stimulate demand. Limited demand entails high prices, and an over-supply may have to be thrown away, because not salable, and the loss must be charged upon the part that is sold.

Mr. Fernow went on to give the cost of production of the seedlings in the Government Forest Nurseries in Germany, tabulating the elements which enter into the cost, and comparing them, so far as possible, with the conditions in this country. These tables were most instructive, but we have not space to reproduce them here. The conclusion of the whole matter was that the main service that the nurseryman can do for forestry is to provide reliable plant-material as cheaply as it can be done consistently with his own prosperity.

SCIENCE AND PRACTICE.

Mr. Thomas Meehan said that it had been fifty years since he wrote his first article for a horticultural paper, and it seemed to him, although horticulture had made rapid advances in all of those years, that it had not progressed as far on the scientific side as it ought to have done. As a practical example of some scientific truths, upon which good practice is based, he instanced the fact that fibrous roots live only a year. They do their work and then die. Where there are a hundred small roots now about a young tree there will be in a few years only a few large ones radiating from it, like railroads on a map. These big roots alone have the strength to send out fibres, and the root is of no value to the tree until new white fibres are growing. Therefore, it may be that a mass of fibrous roots in a tree for transplanting is injurious. They are weak, they have no vital power to put out rootlets, and they may keep the soil from contact with the big roots, which, therefore, do not find the proper medium in which to throw out feeding roots.

Another fact which observation teaches is that roots die in exact proportion to the amount of tops that are cut off. If a tree is pollarded nine-tenths of the roots may die and then invite

a fungus which spreads to the living roots. It is said that the branches which sprout from these pollards grow strongly because the roots are stronger below them, but in fact they grow from the food stored up in the trunk, just as shoots three or four feet long often grow out of logs which lie by the wayside. Generally pollarded trees die after this operation has been frequently performed. Look, for example, at an Osage Orange hedge. If one of the trees at the end is allowed to grow it will make a trunk as big as a man's body in twenty years, while the hedge plants of the same age, their vital power being weakened by constant cutting, are no larger than a man's wrist. Of course all pruning is not to be condemned, although it does weaken the vital power of the plant. We prune for other purposes than to make long-lived trees.

AUTUMN DELIVERIES OF NURSERY STOCK.

Mr. G. E. Meissner, of Missouri, in speaking of the shipment of nursery stock in autumn, said that in recent years the practice of contracting to deliver this stock very early in the fall has become so prevalent that the young trees are often dug for fall planting before the wood has fully ripened. They are torn from the ground while the young rootlets are still at work, and the leaves are stripped from them while they are still busy digesting the sap, and, of course, they are in no condition to endure the winter. Yet nurserymen often advertise deliveries as early as the 20th of September, because they say people demand it. It is for this reason, perhaps, that fall planting is coming into disrepute. Of course, planting which may be seasonable in Ohio is not so in Tennessee, and there is a great difference in the quality of trees in this respect. For example, a Currant-bush or Cherry-tree can be dug and shipped when a Wild Goose Plum would be ruined.

After some discussion, the Convention passed a resolution in which they disapproved and protested against the lifting of trees before the leaves had ripened and the wood had attained a proper degree of maturity, and requested all members to dis-courtenance and discourage this practice.

Massachusetts Horticultural Society.

THE Rhododendrons made a brilliant display at the Horticultural Hall, Boston, on the 7th instant. The chief exhibitors were Messrs. Nathaniel T. Kidder, of Milton; Francis B. Hayes, of Lexington; John L. Gardner, of Brookline, and H. H. Hunnewell, of Wellesley. The following selection gives the largest and best-formed trusses, with a good range of variety: James McIntosh, Michael Waterer, Princess Mary of Cambridge, Lady Grey Edgerton, Henry W. Sargent, Sherwoodii, *Purpureum grandiflorum*, *Delicatissimum*, Sir William Sebright, Charles Dickens, Sappho, The Queen, Sir Joseph Whitworth and Helen Waterer. The show of hardy Azaleas was rather weak and the varieties insufficiently distinct. It seemed a pity, however, to send so much of the plants with these flowers when less would have served the purpose as well.

The large white inflorescences of the old-fashioned Snow-ball, and the smaller, though more numerous, ones of the Japanese species, were very attractive. A single flowering branch of Laburnum was sufficient to show the highly decorative character of this elegant tree, and sprays of large-flowering varieties (not named) of Clematis suggested the utility of these climbing plants. Conspicuous among the exhibits of herbaceous plants were Oriental Poppies, Irises, Columbines and Day Lilies. The miscellaneous exhibits included a plant in bloom of the interesting and beautiful *Utricularia nelumbifolia*; flowering branches of that magnificent greenhouse climber, *Bougainvillea glabra*, and flowers of *Tacsonia Van Volxemi*, which is a splendid climbing greenhouse plant, with large crimson flowers.

Notes.

Green Corn is coming into market from the Carolinas, Raspberries from Norfolk, Watermelons from Georgia and Peaches from Florida.

The great Palm which stood in the Gardens of the British Embassy at Rome blew down during a late gale. This was not only the tallest Palm in Rome, but it was memorable because pierced by a cannon-ball during the attack on the city in September, 1870. It was strapped with iron where it had been struck.

The Central Park has never looked so well as it does this year, and much of the improvement comes from the removal of the decaying conifers, chiefly Norway Spruces, which last season disfigured its beauty. No one misses the thousands

that have been cut, not even the misguided enthusiasts who tried to impede the work of the park authorities.

Among the Hybrid Perpetual Roses blooming out-of-doors not one has behaved better this season than Ulrich Brunner, with its full and perfect buds, exquisite color and rare fragrance. The Baroness Rothschild, too, is blooming unusually well, and so are those excellent sorts, Magna Charta and Paul Ricaut. If they would only bloom again, as do other hybrids which have no China blood in them! John Hopper, Mrs. Charles Wood and Rev. J. B. Canim are uncommonly good, and Moss Roses never bloomed better.

The folly of protesting against the popularization of botanical names in the belief that vernacular ones are all-sufficient was recently shown in an article in a horticultural paper which spoke of the poisonous qualities of some of our common plants. "Ivy" and "Dogwood" were named as plants which it is dangerous for many persons even to handle. Of course the reference was to the so-called Poison Ivy and Poison Dogwood, neither of which has any relationship to the plant whose name has been given it. Both belong to the Rhus family, and, indeed, as Rhus is synonymous with the vernacular Sumach, there is no reason, save popular perversity, why they should not always be called Poison Sumachs. Such a misleading use of terms as we cite, where even the qualifying "Poison" was omitted, may well decrease the pleasure of timid readers as seeming to warn them against two kinds of beautiful and wholly innocuous plants.

A convenient little pamphlet on the treatment of plant-diseases has lately been sent out by the section of vegetable pathology of the Department of Agriculture. At various times we have called attention to the remedies as they have been tried and approved; but here are grouped together, in a score of pages, the remedies for diseases of the Grape, the powdery mildew of the Apple and the leaf-blight of the Pear by B. S. Galloway; Professor Maynard's experience with mildew of Lettuce and the Rose; Professor Halsted's study of gall-fungus and scald of the Cranberry; Professor Goff's application for Apple-scab, and the hot water remedy for smut in Oats by Professor Kellerman. The pamphlet also contains notes on the effect of certain fungicides upon the vitality of seeds, upon the contagious character of Peach yellows, upon copper salts as fungicides, and upon different spraying apparatus. The bulletin is an extract from the *Journal of Mycology*, vol. vi., No. 1.

In "Fort Ancient," a volume recently published by Mr. Warren K. Moorehead, of the Smithsonian Institute, a full description is given of the prehistoric remains in Warren County, Ohio, which are popularly called by this name. They seem to have formed a vast fortress of earthen walls nearly four miles in circumference, and a plausible supposition makes them not more than nine centuries old, and the work of the Mandan Indians, a branch of the great Dakotan or Siouan race. One of Mr. Moorehead's chief aims in writing his book was to advocate the preservation of the vast relic by the formation of a sort of public park similar to that which contains the more famous "Serpent Mound" in the same state now under the guardianship of the Peabody Museum of Archaeology. The interesting illustrated description of this Serpent Mound Park, which was recently published in the *Century Magazine*, should certainly excite even those who have not read Mr. Moorehead's book to interest themselves in the plan he proposes.

Since Professor Halsted's article on the Oak blight, in another column of this issue, was put in type we have noticed that the Sycamores in Central Park are generally affected. Some leaves from a diseased tree on Jersey City Heights were sent to New Brunswick, and the blight is identified as the true *Gliosporium nervisequum*. We have observed that the blight has extended throughout northern New Jersey and should be obliged if correspondents would report from other places. Professor Halsted writes that there is little hope from the application of fungicides, because the trees are large and the foliage cannot be easily reached. The injury to the foliage is so serious that the trees cannot last many seasons if the disease persists. The advice to cut down the badly affected Oaks and Sycamores, in the hope of exterminating the disease, seems rather radical, although Professor Halsted suggests it. There is no certainty that this remedy would be effectual, and the fungus itself could inflict no greater harm, because it would mean the extermination of the Sycamore in this region. There is always the hope that diseases of this sort, after running through a cycle, will be checked in some unknown way, disappearing as mysteriously as they came.

In the June number of the *North American Review* Ouida writes entertainingly about gardens, taking for her text a passage in which Lord Lytton reminds us that whoever has a garden has one chamber roofed by heaven, in which the poet and philosopher can feel at home. The seclusion and homelikeness which distinguish every real private garden from a public park are dwelt upon as its essential charm. It follows naturally that a place dedicated to retirement and reflection should be simple and natural, and this gives the author an argument against artificiality of construction, elaborateness of decoration and over much sweeping and pruning, and it justifies a plea for old-fashioned flowers, about which hang memories of a happy childhood. And here is a passage which we cannot forbear to quote: "Of all emotions which give the nature capable of it the purest and longest-lived pleasure, the sense of the beauty of natural things is the one which costs least pain in its indulgence, and most refines and elevates the character. The garden, the meadow, the wood, the orchard, are the schools in which this appreciative faculty is cultured most easily and enjoyably. Dostoevsky may find food for it on the desolate steppe, and Burns in the dreary plowed furrow; but to do this, genius must exist in the man who feels: it is to the ordinary sensibilities, the medium mind, the character which is malleable, but in no way unusual, that this training of the eye and of the heart is necessary; and for this training there is no school so happy and so useful as a garden. All children, or nearly all, take instinctive delight in gardens: it is very easy to make this delight not merely an instinctive, but an intelligent one; very easy to make the arrival of the first Crocus, the observation of the wren's nest in the Ivy-hedge, of the perennial wonders of frost and of sunshine, of the death and the resurrection of Nature, of the deepest interest to a young mind athirst for marvels."

Monsieur Franchet publishes in the *Revue Horticole* of May 16th an important paper on the new species of *Lespedeza* recently discovered in western and south-western China. His remarks on the climate of this last region are of special interest, as this is now botanically one of the most interesting regions of the world from the great number of remarkable plants it contains, some of which, too, seem destined to play an important part in the decoration of gardens. "The temperature of the provinces of south-western China," Monsieur Franchet says, "and particularly that of Yu-nan, is not in effect as high as might be supposed if the question of latitude only is considered. In that region, which is absolutely continental, high altitudes reduce the temperature, which might otherwise be excessive on account of its neighborhood to the tropics. It is easy to understand that a region broken in all directions by mighty mountain chains, some of which, like the Tchangan, reach twelve to eighteen thousand feet, as is the case with several summits of the chain Li-kiang, and are covered by snow and eternal ice, although it is placed between the twenty-sixth and twenty-eighth degrees of north latitude, cannot have a uniformly high temperature; in fact, the vegetation of Yu-nan bears the mark of an exceedingly variable climate, although certain valleys, on account of their position and direction, attract heat and so become the refuge of a considerable number of tropical species, while the slopes of the mountains exposed to the north are occupied by a flora which resembles that of temperate regions, and where forests of *Rhododendrons* and of *Oak* are the prevalent features (*Quercus Bungeana* and *Q. dentata*, both species of which grow also in the neighborhood of Peking). It happens, therefore, that the greatest surprises greet the explorers of the vegetation of this region, who can in the same day pass from the plants of the tropics to those of the coldest regions of the world, gathering in the morning the *Casalpintia sepiaria*, for example, and end their day before little thickets of *Rhododendron fragrans*, the ordinary inhabitant of the polar region."

The Oldest Locust-tree in Europe.....	311

The Locust Tree.

THERE is not in Europe a more interesting tree for Americans to visit than the venerable Locust in the garden of the Museum of Paris, whose portrait is reproduced on page 311. The first of its race to grow in the soil of Europe, it has survived for more than two centuries and a half the wars of the elements and the social cyclones which have swept over it. The seed from which it sprung was planted in 1635 by Vespasian Robin, gardener of Louis XII., in the Jardin du Roi, now called the Jardin des Plantes. Vespasian Robin was the son of a gardener more famous than himself, Jean Robin, who had charge of the Royal Gardens under Henry of Navarre; and it was for the elder Robin that Linnæus, more than a century after his death, named the genus Robinia, to which our Locust-tree belongs. Little is left of the old tree but the shell of the trunk and a few feeble branches which clothe themselves year after year with leaves and flowers, testifying to the wonderful vitality of the Locust-tree and to the care which has been bestowed upon this specimen by the authorities of the garden, the most interesting in the world, perhaps, in its historical associations with men famous in the annals of botany.

The Locust-tree (*Robinia Pseudacacia*) has excited, from a cultural point of view, more interest than any other inhabitant of the American forests. There is no other North American tree about which whole volumes have been written, and no other of our trees has been so enthusiastically praised or so widely scattered by cultivation.

The earliest account of the Locust-tree was published in 1640 by Parkinson in his classical "Theatrum Botanicum," it having been cultivated in England about that time by the Dutchman John Tradescant, a great traveler and botanist, who held the position of gardener to Charles I. Evelyn, in his "Sylva," published in 1664, records the fact that the Virginia Acacia thrives in the King's new plantation in St. James Park; while his great French contemporary, Duhamel, gave a few years earlier specific directions for its cultivation. A hundred years later the Locust had so grown in esteem in Europe that something was said

about it by nearly every writer who discussed rural economy or the possibility of increasing national wealth through the cultivation of exotic trees. The first book devoted entirely to the Locust was published in Paris in 1803. It is a small octavo of 314 pages, and is entitled "Lettre sur le Robinier connu sur le nom impropre de faux Acacia." It was written by M. N. François de Neufchateau, a Senator and member of the Institute. This work contains the essence of all that had been previously published about the tree in France, and a great deal of information relative to its culture and uses. A translation of portions of Monsieur François' essay is published in an English book on the Locust, which appeared from the pen of W. Withers, of Holt, in Norfolk, in 1842, under the title of "The Acacia-Tree: Its Growth, Qualities and Uses." William Cobbett, however, better known perhaps as the vituperative political essayist, Peter Pindar, than as an enthusiastic and successful planter of trees, did more by his writing and example than any other man to make known the value and spread the cultivation of the Locust-tree.

Cobbett, during a forced residence in the United States from 1817 to 1819, occupied himself in farming on Long Island, where he established a small nursery for the propagation of fruit and timber-trees. It was at this time that he came to the conclusion "that nothing in the timber line could be so great a benefit as the general cultivation of the Locust." On his return to England he carried a small package of the seeds of this tree home with him and began the systematic raising and selling of Locust-trees, his total sales amounting to more than a million plants. This he tells us in his book called "The Woodlands," which, in some respects, is the best book on tree-planting which has been written in the English language. The author in his preface gives his reasons for having written it: "Many years ago," he says, "I wished to know whether I could raise Birch-trees from the seed. I looked into two French books and into two English ones without being able to learn a word about the matter. I then looked into the great book of knowledge, the 'Encyclopædia Britannica'; there I found in the general dictionary, 'Birch-tree, see Betula, Botany Index.' I hastened to Betula with great eagerness; and there I found, 'Betula, see Birch-tree.' That was all; and this was pretty encouragement to one who wanted to get, from books, knowledge about the propagating and rearing of trees." There are tree-planters of the present generation who turn to the literature on the subject with results which are hardly more satisfactory. Cobbett's book has long been out of print, but no other work gives such clear and specific direction for rearing and planting trees, and there are portions of it which might well be reprinted for general circulation.

Cobbett's enthusiasm for the Locust-tree, and his zeal in propagating it, caused it to be planted generally in England in his time, and the fashion, as is often the case with English fashions, crossed the Atlantic, and fifty or sixty years ago no tree was so often planted in this country. Remnants of these old plantations may be seen up and down the Hudson River and in the neighborhood of all our seaboard cities; and the Locust is now fairly naturalized in a large part of the country east of the great plains, although originally its range was a comparatively restricted one, it being found only in the forests of the Alleghany Mountains, from Pennsylvania to northern Georgia, and, doubtfully, in a few isolated stations west of the Mississippi River. So far as the United States is concerned, however, the Locust-tree has not fulfilled the hopes of the early planters. It is preyed upon in this country by a horde of insects who bore into the trunk and destroy the trees or the value of their timber, and the prophecy of the younger Michaux, that the Locust-tree would become more common in Europe than in its native country, has probably been fulfilled.

It is, however, one of the few American trees, if not the only one, which has become really naturalized in Europe, and there is no other exotic tree which travelers in central

Europe see more frequently. This is due, in part, to the fact that it has been planted everywhere along the lines of railroads to hold the soil on the embankments, and because it is the favorite tree for the embellishment of the grounds surrounding the stations.

Long cultivation of this tree has given birth to many varieties, and of these the one known as the Parasol Acacia, with a dwarf, compact, spherical head, usually grafted as a tall standard, is one of the most popular ornamental trees in Europe, where it lines countless miles of roadside and adorns innumerable villa-gardens.

The great value of the Locust-tree is found in the wood which it produces. This is heavy, exceedingly hard and strong, very close-grained, and capable of withstanding for a long time the effects of decay when placed in contact with the ground. This makes it one of the best woods known for fence-posts; it has many uses in ship-building, and is preferred to the wood of all other trees for tree-nails, for which purpose it is largely used. It grows rapidly from seed, which is produced in the greatest profusion, and it will adapt itself to almost every kind of soil. The rapidity of its growth is great, and thanks to the lightness of the shade cast by its compound leaves, it does less injury than most other trees to crops growing beneath its branches. The Locust is a good hedge-plant, too, and the fragrant white flowers are very beautiful. These are the qualities which have made the Locust popular, and were it not that it is so liable to the attacks of insects, the planters of the present day would be able to endorse all that Cobbett claimed for it.

An illustration in a recent issue of *The Garden*, London, indicates what delightful effects can be produced by naturalizing hardy spring-flowering plants in the grass. It represents a forest-scene in the grounds of Dunrobin Castle, with the turf about the trunks of the old trees thickly studded and completely carpeted with Snowdrops, which have been growing there from time immemorial.

There is certainly no more delightful and satisfactory form of gardening than that which naturalizes hardy plants, especially the plants which flower in early spring when every flower is doubly valuable. A thousand bulbs of the Poet's Narcissus, of the Snowdrop, or of the Squill, or of the Crocus, will produce infinitely more pleasure if they are planted in some wild spot by the edge of a wood or of a wood path, than the same number of plants are capable of giving in a formal flower-bed or border. Wild gardening, if the term is a permissible one, is the easiest and most economical of all forms of the gentle art. Once the plants are established in the proper soil and in the right situation, they require no further thought or care. All they need is to be let alone and to be allowed to go on growing and increasing and producing their flowers year after year.

The earlier in the autumn bulbs which produce their flowers in the spring can be set in the ground, the sooner they will become established and the better the results which they will give. This is the time, therefore, to study the lists of the dealers in plants of this sort, to determine which are to be planted and to order the bulbs.

There are a few rules which can be safely followed in gardening of this character. The most important of all is to select only such pieces of ground for planting with spring-flowering bulbs as need not be mowed until they have thoroughly matured their leaves, as the early cutting off of the leaves will weaken and finally destroy the bulbs. The turf of a lawn cut early and regularly with a lawn-mower is not, therefore, a suitable place for bulb-growing. If the grass is not cut until after the middle of June the leaves of nearly all the spring flowering species, even such late blooming ones as the Poet's Narcissus and the Wild Hyacinth, will be ripe enough to cut without injury; so that such plants can be naturalized in ordinary hay-fields, if it is desirable to do so, with perfect safety. Some judgment, too, must be used in selecting the plants to be employed in this sort of gardening. Those unchanged by

cultivation are better suited for the purpose than plants which the gardener has long worked over. The double Daffodil looks out of place by the borders of a wood walk, while all the single Narcissus appear perfectly at home in such a situation. The wild Hyacinth and the other Squills, the Snowdrops and the Crocuses, never appear too fine for any bit of natural scenery, while a garden Tulip or a garden Hyacinth, gaudy and beautiful although they be in a formal parterre, spoil with their artificiality the simple beauty of a woodland glade or of a smiling meadow. In our climate, where the enjoyment of the earliest spring-flowering plants is often interfered with by melting snow and by the mud of late March and early April, few wild plants can be used with more safety and with a greater prospect of pleasure than the Poet's Narcissus and the wild Hyacinth (*Scilla campanulata*). The two flower at the same time and the blue bells of the latter make the most charming contrast with the pure white flowers of the former. They flower here simultaneously, too, with many of the native plants which are most desirable in the garden, such as the Trilliums, the Phloxes and the early Lady's Slippers.

So, to the owners of gardens we can only repeat what has been said so often before in these columns, that if they want to obtain the greatest amount of pleasure with the smallest outlay of labor and money, let them plant hardy bulbs, and the more the better; and the sooner their plans are laid and their plants ordered, the better will be their chances of success.

The Kecskemet Heath.

HEATH—*Heide*—is in Germany a generic term for any stretch of sandy, uncultivated country, whether it be covered only with grass and scrubby, low vegetation or more or less generally with poor trees. Such a heath formerly stretched for many miles around the town of Kecskemet, in Hungary—an apparently limitless expanse of grass and shifting sand, which gave rough pasturage for herds of long-horned cattle and plethoric swine, guarded by peasants who, summer and winter, wore their characteristic sheep-skin coats, with the wool outside, and by the huge wolfish Hungarian sheep-dogs. A writer in the *Illustrierte Gartenzeitung*, of Vienna, tells, however, of the transformation which this semi-desert has undergone in recent times. Even in approaching Kecskemet by the railroad, he says, one is struck by this transformation, the road running for miles between embankments beyond which, instead of the former waste of drifting sand, bare of trees or shrubs, now extend luxuriant gardens, giving evidence of the most careful cultivation, vineyards and orchards succeeding on each other, or, most often, mingling their allied products. Closer observations only increase the surprise of the visitor. A half hour's drive from the suburbs in any direction takes him into real forests of fruit-trees, which cover many thousand acres of land, and, in their little clusters of farm-houses and peasant inns, sustain a population of 20,000 persons of the true ancient Magyar stock.

This great steppe, whose soil was of the coarsest sand, was to a large extent the property of the town, the municipality owning sixteen square miles—more, says our author, than the area of some of those little principalities into which the German kingdom was formerly divided. In order to redeem this district, the town, some thirty or forty years ago, granted a portion of it to its inhabitants on condition that it should be cultivated, recommending especially the planting of orchards. Now Kecskemet fruit is famous not only in Austria but in Russia, and in a good year brings the dealers of the town a profit of half a million dollars. Broad highways run for miles in all directions from the town, planted with hedges and avenues. It is interesting to note that the only trees our author mentions in this connection are of American origin. The Locust, he says, is most generally employed, but the Gleditschia (Three-thorned *Acacia*) is also much used, having proved an excellent protection against the storms which sweep over the heath and the drifting of its sands. Apples form the chief crop, although apricots are grown in such quantities that whole trains filled with them are dispatched during the season to various parts of Germany and Russia. Pears are likewise grown, and cucumbers, melons and paprikas, of which a great specialty is made. But the grape vies with the apple in importance. The vines are grown in the way usually adopted in southern Germany as well as in southern France, being closely

set without stakes. They cover the ground in the orchards between the trees, and are also trained on espaliers or fences along the highways and to form the divisions between the fields. The sandy soil seems to have protected them against the ravages of the phylloxera, and the quantity of wine they yield is large and ever increasing, although its quality is not so good as that produced on the hills in other parts of Hungary. When the development of this industry was first thought of the government planted an experiment station of large extent with six hundred varieties of the Grape, American as well as European sorts being tried, and with this was combined an experimental orchard. To-day the municipality also owns a "Town-garden" containing about one thousand fruit trees of the finest sorts, and itself administers large tracts of the former heath. But it is not more interested in improving its own property than in spreading information among private cultivators and encouraging them to new efforts. With these ends in view it has established a large agricultural school and in fourteen of the scattered little communes on the heath has founded village schools for the education of the neighboring peasant children. During the winter they are taught in the usual way from books, but in the spring the teacher grasps spade and hoe, and in the extensive garden that adjoins the school, gives practical instruction in horticulture.

In short, within forty or fifty years, at a comparatively small outlay of money, a vast, forbidding desert has been transformed into a garden blossoming like the Rose, where no foot of ground is wasted, and where the once half-nomadic, half-savage population is steadily growing in intelligence as well as in wealth. And the town to whose municipality the credit for the work must be given, has itself profited by the increase of trade to a degree that is said to be fairly surprising. Intelligent direction and concerted effort, without any great expenditure of money, have accomplished these results.

Who is the Vandal?

MR. FERNOW is writing some tracts on Tree Topics in *Kate Fields' Washington*, and the first of the series is devoted to the education of those whose misguided affection for single trees leads them to shudder when any proper thinning out of park plantations is attempted. In the grounds of a public institution in Washington, planted by Downing, the trees are choked and disfigured for lack of proper care, and yet the officials will not allow a tree to be cut, being restrained, it is said, by sentiments of reverence. "You propose to cut a tree in this park?" cries the indignant enthusiast. "You are a vandal!"

"My friend," replies the critic, "it is you who are the vandal. It is you who lack a civilized conception of fitness and beauty. It is you who do not see that by allowing this tree to stand you are preventing the development of its more valuable neighbor. It is you who, from a purely sentimental motive which you call reverence, will suffer your pets to choke and stunt each other till the beauty of a whole group is marred, in which the doomed member has outgrown its usefulness."

"Mr. Downing adapted the groups of trees and the shrubbery to make a pleasing picture at the time. He knew that the individual parts could not always retain their relation to the whole, and he never intended that they should. May his æsthetic spirit and his conception of the fitness of things descend upon those of our public officers by whose hands the beauty of our national capital may be either preserved and improved, or marred and destroyed."

Danger to Orange Groves in California.

AN important discussion is now going on respecting Florida-grown Orange-trees, which have been sold by thousands in California. Several nurserymen who found that the margin of profit was large, began to bring Florida Orange-trees to California several years ago, and at last established nurseries in Florida. The purple, or oyster-shell scale (*Mytilaspis citricola*) has been discovered on Florida stock in southern California, and so have the "long scale" (*M. Gloverii*), and the "chaff scale" (*Parlatoria Pergandii*), all of which are illustrated and described in Hubbard's "Insects Affecting the Orange." The "chaff scale" is often found on Orange-trees imported from China and Japan, and the inspectors have ordered more than one affected lot of trees to be destroyed. The Florida "red scale" (*Aspidiotus Ficus*) has also appeared in southern California on Florida stock, and on trees brought from Brazil. Professor Couquillett is reported in the *Rural Californian* as saying that ten new pests have been found this

year on imported stock. The newspapers and horticultural societies are taking up the matter and urging prompt measures to destroy every infected tree.

An orchardist at Santa Ana writes about an allied species of red scale, the *Aspidiotus aurantii*, in the following vivid manner: "The red scale is as dangerous and infectious to fruit interests as small-pox is among human beings. If any one wants to know what a destructive thing it is, let him come down in this vicinity and visit Orange. It is a pitiful sight to see what ruin has been caused by the indifference of the people when the pest first came into this valley. When I first saw Orange, in the fall of 1884, I thought it the garden spot of America. I never shall forget the luxuriance of the acres of Orange-orchards, and the prosperous looking places. There were then shipments of many car loads of Oranges from Orange station every spring, and there were dozens of men who got from \$2,000 to \$4,000 a year for their Orange-crops. The red scale came there in the spring of 1885. People talked a little about it, and a few said the pest would be serious unless stamped out at once. Their fears were ridiculed, and every one went on in an easy, indifferent way, while the little red scale multiplied, spread and devoured, until at last the people saw acre after acre of Orange-trees dead and dying. In Orange to-day, where there were hundreds of fine orchards five years ago, the land is now covered with the decaying stumps of Orange and Lemon-trees."

This sort of thing stirred up the Pomona and Riverside people, and their Inspectors have been at work for two months, examining every tree in the district, whether set in nursery or orchard. They long ago quarantined against the infested districts of California, and now the quarantine will undoubtedly be extended to all Florida-grown trees.

Legislation Against Fungous Diseases in New Jersey.

LAST year a large portion of my time was occupied in an investigation of the diseases of the Cranberry, the results of which were published in Bulletin 64 of the Experiment Station. Aside from the "Scald" of the Cranberry (sometimes called the "Rot") the next worst enemy is the Gall Fungus. This last takes a second place only, because it is at the present time very limited in the area upon which it was seen. A single large bog only was found infested with it, but from a study of the habits of the fungus it is evident that it spreads with the water during spring, and if it should effect an entrance into a bog it would soon develop in all parts through which the contaminated water flows. Fortunately, the water from the infested bog in question does not flow into any other bog or it would most certainly carry the disease there with it. It is, however, likely that the germs may be taken from one bog to another by birds and other animals, and by winds drifting the diseased leaves over the crust of snow upon fields in winter. The danger of this last mode of spreading infection is increased by the fact that several kinds of plants closely related to the Cranberry and growing upon the borders of the bog are also infested, and some of them drop their leaves in autumn.

The Gall Fungus has proved almost ruinous to the infested bog, and, because of this, and that it is as yet so circumscribed, the following law has been passed to cover all such cases of fungous diseases:

Whereas, The officers of the State Agricultural Experiment Station have discovered certain new fungous growths that threaten serious injury to important agricultural interests of the state, therefore,

1. Be it enacted by the Senate and General Assembly of the State of New Jersey: That when the officers of the State Agricultural Experiment Station shall discover any new fungous growth which is doing injury to plants or vines, and while the same is confined to limited areas, they are hereby authorized and empowered to enter upon any lands bearing vines or plants so affected, and destroy the same by fire or otherwise as they shall deem best.

2. And be it enacted, That any damage to private property resulting from the operation of destroying the said fungous growth by the officers of the state shall be certified to by them and the amount of damage paid to the owners thereof from the same fund and in the same manner as is paid to owners of diseased animals by order of the State Board of Health.

3. And be it enacted, That expenditures under this act shall not exceed one thousand dollars in any one year.

4. And be it enacted, That this act take effect immediately.

Approved May 23d, 1890.

It will be seen that, according to this act, means can be taken

for the extermination of the Gall Fungus upon the infested Cranberry-bog. In this case it will mean not simply the burning or drowning of the diseased Cranberry-vines, but the destruction of those species of shrubs along the shore of the bog that are attacked by the galls. A mildew, quite fatal to Cucumbers under glass, was recently found within the state, and this may prove to be another case that can be successfully handled under the new law. In like manner, within the past fortnight, the station botanist has found a parasitic fungus unknown before in this country (*Peronospora Rubi*, Rabenh.) upon the cultivated Raspberry. This will need careful watching, and if found destructive, and, at the same time, limited to one garden, it can be eradicated. A larger field is already open for the exercise of the law; for example, the destruction of Plum and Cherry-trees already worthless from the ravages of the black knot, especially of those growing half wild in the roadways.

Plant Note.

Hybrid Firs.

Monsieur E. Bailly, writing in the *Revue Horticole*, describes under the name of *Abies insignis* and *Abies Nordmanniana speciosa* two hybrid Firs which have appeared in European gardens. The first originated in the nurseries of Monsieur Rennault of Bulgnéville, in France. It was raised from seeds of a tree of *Abies pectinata* grafted with *Abies Pinsapo* in 1848-49. The remarkable appearance of some of the seedlings raised from this tree led their owner to suppose at first that the graft had been effected by the stock, and that they were really the result of a graft-hybrid. Afterward, however, it was remembered that a tree of *Abies Nordmanniana* growing at a distance of four or five hundred feet produced male flowers, so that it is not improbable that the belief that the hybrid is the result of a cross of the flowers of *A. Pinsapo*, impregnated by the pollen of *A. Nordmanniana*, is correct. Perhaps not the least interesting part of the matter is that the hybrid plants have proved hardier than plants of *A. Pinsapo* growing with them. Speaking of the plants, Monsieur Bailly says "the affinity of the hybrid with *Abies Nordmanniana* and *A. Pinsapo* does not appear to be doubtful. It unites the two species by its botanical characters and establishes between them a sort of union. The habit of the trees, the arrangement of the branches, the color and the arrangement of the leaves, recall those of *A. Nordmanniana*, but the thickness of the leaves and their coriaceous consistency are rather those of *A. Pinsapo*. The arrangement of the leaves is intermediate between those of the two parents. In form their apex is not acuminate or often mucronate, like that of the mother-plant; nor truncate, like that of the pollen parent, but is subacute or obtuse. From an ornamental point of view this hybrid is not without value. It is, on the contrary, a very handsome tree, elegant and vigorous, of good habit, and one to which I wish to invite the attention of lovers of conifers."

The second of these hybrids, *Abies Nordmanniana speciosa*, was produced by Monsieur Croux, the nurseryman, of Aulnay, near Sceaux, in the neighborhood of Paris, who fertilized female flowers of *A. Nordmanniana* with the pollen of *A. Pinsapo* in 1871 or 1872, care having been taken at the time to remove from the plant of *A. Nordmanniana* operated on all the male flowers before they reached maturity. Another hybrid *Abies* exists in the garden of Monsieur H. de Vilmorin—a cross between *A. Pinsapo* and *A. Cephalonica*. Monsieur Bailly asks, in view of the rapid and vigorous growth of these three hybrids, if there may not be an advantage from an economic point of view in using them or other hybrids in forest plantations on a large scale. It is not, of course, improbable that a hardier, more vigorous and more valuable race of timber-producing trees may be obtained by hybridization, although until such a race could be fixed by long cultivation it will be necessary to resort to grafting in order to secure plants of the mixed breed.

New or Little Known Plants.

Cypripedium Philippinense.

OUR photograph of this interesting species on page 309 was made from a plant in Mr. Hicks Arnold's collection in this city, where it flowered in March of the present year. This handsome species was introduced from the Philippine Islands by Mr. John Gould Veitch many years ago, and long remained rare in cultivation. It is now more common, having been found by Roeberlen, a collector of

Sander & Co., in a region which has not been made public. The plant is generally sold and known in gardens as *Cypripedium Roeberlenii*, although there is apparently little doubt of its identity with the species from the Philippine Islands, which was, of course, described much earlier. The flowers, which are about three inches across from tip to tip of the upper and lower sepals, are distinguished by a broadly ovate, pointed, whitish upper sepal striped with dark brown-purple, by a lower sepal, white with green veins, and by ribbon-like, pendulous petals furnished with short hairs and five or six inches long. They are twisted, yellow at the base, and dull, reddish purple along most of their length, with the exception of the apex, which is purple. The buff-yellow lip is faintly streaked with brown.

This species grows in one of the hottest regions of the world in the full blaze of a tropical sun and exposed to the force of tropical storms. It is therefore interesting to find that it adapts itself to cultivation, and that it will flourish when transferred to a city greenhouse, like the one in which Mr. Arnold grows his collection and which contains several fine specimens of rare plants, and which is instructive and interesting as showing what can be accomplished in a comparatively small greenhouse in which it is impossible to give to each plant the peculiar conditions of heat and light which are supposed essential to its welfare. The fact that a plant which theoretically ought to be as difficult to cultivate as *Cypripedium Philippinense* flourishes in conditions which seem equally favorable to a number of other plants which grow naturally under very dissimilar climatic conditions, and which are usually considered difficult to manage, shows very conclusively that the cultivation of Orchids is not such a delicate matter as many persons suppose, and that any one with a moderate sized greenhouse can grow successfully a large variety of the very best of them.

Mr. Arnold will, we trust, pardon us for thus calling attention to his greenhouse and its contents. Our excuse for doing so is our desire to point out that there are a great many people living in cities who are fond of flowers and have the means for gratifying their love for them who can with the aid of a small glass structure placed on one of the outbuildings of their dwellings gratify their tastes by cultivating many interesting plants. There certainly can be no more delightful adjunct to a city mansion than a small greenhouse or conservatory, and the pleasure it is capable of affording will increase in proportion as the owner himself understands his plants and studies their requirements.

Foreign Correspondence.

London Letter.

N YMPHÆAS are especially attractive now at Kew. A circular tank thirty-six feet in diameter is filled with the leaves and flowers of a large number of kinds. Best of all is *N. Zanzibarensis*, one of the Stellata section, but much superior to any other in the group. Its flowers are ten inches in diameter, and are in the form of huge cups colored deep purple-blue, the base shaded with crimson and the centre occupied with golden anthers. It is about five years since this plant made its debut at Kew, but its full dimensions have never been seen in England before this year, the enormous size of the flowers being the result of allowing the plant a bed of rich soil three feet across by two feet deep, instead of growing it in a large pot as hitherto. Almost as striking in size and color is the beautiful yellow-flowered *N. tuberosa flavescentis*, its blooms as large, as fragrant and charming in color as the most perfect of Maréchal Neil Roses. *N. Lotus*, var. *rubra*, with huge flowers colored rose-crimson, and *N. dentata* (white), *N. Ortgiesiana* (pink), *N. albo-pygmaea* (white), and the various forms of *N. stellata*, from pure white to blue, are all flowering freely, and in the morning at about eleven o'clock they form a magnificent picture. An aquarium well stocked with the best aquatic plants is about as charming as anything in the way of in-door gardening. At any rate, the Water Lily house at Kew is an exceptional attraction to visitors during the summer.

The Azalea garden at Kew is one of its most delightful features during the month of June, when the plants are in bloom.

A large open space, surrounded by magnificent trees, in groups or isolated, with long vistas terminating in views of the lake or of some handsome building, and carpeted with the softest of lawns, is filled with large specimen Azaleas, whose prototypes are wild in your country, but whose colors and fragrance are beyond description. This year the display has been grander than ever. The wisdom of clearing away some large trees which overshadowed the Azaleas, re-forming the beds and replanting the specimens in good soil is now showing itself in a wealth of bloom and intensity of color unequaled by anything else in the garden either in-doors or out. I am told that even in America these Azaleas do not meet with the appreciation which, as seen at Kew, they abundantly merit. Compared with them the garden Rhododendron is stiff and gaudy, whilst in fragrance they are only equaled by our native Honeysuckle. We are immensely proud of our garden of American Azaleas. Amongst them are specimen trees of Magnolias such as *M. Umbrella*, *M. auriculata*, *M. Soulangeana*, *M. conspicua* and *M. cordata*. Some of these are in flower now or are just over. Mr. Gumbleton, of Cork, informs me that *M. Campbelli*, the Himalayan species with enormous flowers colored rich crimson on the outside, would certainly be hardy at Kew. It is one of the grandest of the genus, but hitherto it has been grown under glass in England,

Fig 43.—Cypripedium Philippinense.—See page 308.

although in the south of Ireland there are magnificent specimens in the open air.

Musa Japonica is the name given to a plant which Messrs. Veitch & Sons introduced about ten years ago from Japan, and which has proved capable of out-door cultivation in their nursery at Coombe Wood. A plant of it at Kew, in the winter garden, is now in flower. It is of more than ordinary interest, as it appears to be the *M. Basjoo* of Japanese authors, of which hitherto very little was known. It has a stem ten feet high, leaves as long, a stout, drooping inflorescence, the most conspicuous character in which is the large size of the oval-concave bracts and their tawny brown color. A *Musa*, which has all the striking appearance of *M. sapientum* and which may be grown in a temperature as low as that of an ordinary situation in the south of England, is likely to prove of value horticulturally. The only *Musas* that are ever planted out-of-doors in England are *M. superba*, and its ally, *M. Ensete*, but these are too tender to bear a temperature approaching frost, and must, therefore, be taken in-doors during winter. A second *Musa*, likely to bear a lower temperature than many of the species, is grown at Kew as an unnamed species indigenous in Hong-Kong. Both these *Musas* form suckers freely, and, in positions suitable to them, they would soon form a large cluster of handsome foliage.

An exhibition of plants organized by the Royal Horticultural Society, and held last week in the Temple Gardens, adjoining the Strand, was remarkable in many ways. Hitherto the exceptional efforts of this Society to get together a big display of plants, and to induce a big crowd to go and see them, have been spoilt by bad weather or some other circumstance

beyond control. This time, however, the weather and everything else appeared to smile on the Society, the result being one of the most successful gatherings of plants and people ever seen in London. A peculiarity of the exhibition was the total absence of money prizes—the awards being only cups or medals. It was feared by many that this new departure would prove a mistake. Instead, however, of its effect being a thin show it was, on the contrary, an unusually full one. The nurserymen did wonders, both in respect to number and quality of their exhibits and in the skillful cultivation they displayed. The power and numbers of the nurserymen of England were very strongly revealed in this show. A few, who must be set down as short-sighted, disparaged the exhibition on this account, arguing that it was from purely commercial motives that the nurseryman exhibited. Probably that is true, but the motive of the private gardener or amateur exhibitor who craves for money prizes cannot be much less selfish than that of the nurserymen.

The chief features of the show were the collections of Orchids, Clematis, Rhododendrons, Filmy and other Ferns, hardy herbaceous plants, flowers and fruits. It would be impossible to mention here a tithe of the interesting things shown; indeed, almost every plant of the thousands there had something special to commend it. H. R. H. the Prince of Wales opened the exhibition and spent a considerable time in inspecting the plants and flowers. He afterward expressed his unqualified delight with all he saw. Those who sympathize with the Society in its efforts to win back the influence for good that it possessed some years ago will know how to appreciate the work of the present Council.

Mr. Bull's annual exhibition of Orchids has become an institution in London. Mr. Bull was, I believe, the first to devote a portion of his nursery to an artistic arrangement of Orchids and foliage plants on the same lines as govern ordinary plant-shows. All regular customers and persons interested are invited by card to inspect the show, which continues two or three months in summer. The ordinary time-killer is excluded by a charge for admission, an arrangement found necessary to prevent the houses from being filled with idlers and those people who rush to see anything and everything. The collection of Orchids in Mr. Bull's nursery is one of the richest in England. There are, also, many rare and beautiful Palms, Aroids, Ferns, Bromeliads, etc., to be found in his establishment. With the aid of these Mr. Bull is enabled to make a most attractive display of flowers and foliage. It is, of course, a trade advertisement simply, but it is a most charming picture, nevertheless, for those who are interested in plants, and who find pleasure in looking at a well grown specimen of a beautiful plant, whether in a nursery or in a private garden.

Notes on Shrubs.

THERE are no hardy *Viburnums* which possess more beautiful or interesting flowers than the native Cranberry-tree (*V. Opulus*), also indigenous to Europe and the northern part of Asia. Specimens in the Arboretum raised from seed collected in the mountains about Peking, China, do not show any sufficiently marked variations from our own to entitle them to a separate specific or varietal name.

The large, sterile, marginal flowers in the flat cymes become conspicuously white a few days before the perfect flowers open, which, in ordinary situations in gardens, occurs here about the 1st of June. It is always remarked that the natural species seems much less liable to attack by Aphides than the Snowball or Guelder Rose, which is but a monstrous form of the Cranberry-tree. This susceptibility to injury may be because the sterile Snowball, being perpetually propagated by cuttings, layers or similar modes of division, is less robust and less able to overcome attacks by insects than the fruit-bearing type, which is generally renewed by seed. Where Snowball-bushes are much infested by Aphides the thorough application of kerosene emulsion or a strong decoction of Tobacco will be effectual in destroying them. But it is very important that the insecticide should be sprayed upon the under side of the leaves with considerable force, so that it will penetrate into the folds of the twisted leaves, where the insects are concealed and the work of injury is carried on.

The Japanese Snowball (*V. plicatum*) is to be recommended for its freedom from disfigurement by these troublesome insects; but aside from this quality, it is valuable for its own peculiar beauty. The common Snowball is a more graceful, freer growing plant, which bears its balls of flowers on somewhat pendulous branches, while *V. plicatum* is a rather formal

shrub, bearing its blossoms on short, rigid, lateral twigs. The rough dark green leaves harmonize with the stiff character of the plant and form a beautiful, though scanty, setting for the profusion of snow-white flowers usually produced. These are arranged in more compact and more evenly round "balls" than those of the common species, and they seem of a purer white color. The character of the two species is so different that they should both be grown if possible, but in a small garden, where there is only room for one, *V. plicatum* would generally give the most pleasure. It should be stated, however, that *V. plicatum* is not so stubbornly hardy as the common Snowball, although it thrives very well in good well drained soil in the latitude of Boston. Both species blossom at the same time, but the Japanese Snowball retains its beauty the longest.

Far larger and more handsome than the flowers of either of the preceding species are the large Hydrangea-like clusters borne by *Viburnum macrocephalum*, a form of a Chinese species of long cultivation in Europe, but whose wild type, with a very few sterile outer flowers, has only recently become known to botanists. The individual flowers of the sterile form are very large, and the clusters or "balls" so great and weighty as to hang like a burden on the plant. This is not so hardy as either of the preceding species, but it can be grown in the climate of Boston.

Of all Viburnums in the Arboretum, the native Hobblebush (*V. lantanoides*), which was figured on p. 535 of the first volume of GARDEN AND FOREST, is the earliest to flower, the blossoms expanding during the first days of May. A week or ten days later the earliest flowers of the European Wayfaring-tree (*V. Lantana*) open, and about May 20th the Black Haw (*V. prunifolium*) comes into blossom with large, flat, compound cymes of small whitish flowers. The last species is not very hardy about Boston, yet in a very favorable location it will become a small tree. It is as pleasing on account of its bright shining green leaves as for its flowers, which are of short duration and closely imitated in effect by those of the Sweet Viburnum or Sheep-berry (*V. Lentago*), a larger growing, perfectly hardy, well known native plant, which comes into blossom a few days later.

Viburnum cotinifolium, a shrubby Himalayan species, comes into blossom during the latter part of May. The leaves of this are soft and downy and have a resemblance to those of *V. Lantana*, but the flowers differ in being arranged in a smaller, much more convex cyme. The small corollas are of a delicate pinkish white color and have an appearance suggestive of dainty porcelain. The anthers just before shedding pollen are conspicuously large and yellow. The plants at the Arboretum need a good deal of protection in winter, but they are fairly hardy in more favorable conditions. *Viburnum Sieboldi* (sometimes *V. Japonicum* in nurserymen's catalogues) is a coarse growing Japanese species which blossoms at the end of May or in early June. The small white flowers in large, flat, rather loose cymes look much like those of Elderberry. The leaves are large, thick and rough, and when bruised they emit an odor quite disagreeable to most people. Fruit is produced sparingly here, but strong, vigorous plants are procured by grafting on stock of the Arrow-wood (*V. dentatum*), a common native species which does not begin to bloom until the middle of June. *V. pubescens*, another native species, is earlier and loses its flowers by the time those of the Arrow-wood open. As ornamental plants in a shrubbery both of these species are superior to *V. Sieboldi*, which may be called more peculiar than beautiful.

The Withe-roads (*V. nudum* and *V. cassinoides*) are so closely alike as to be identical so far as their horticultural value is concerned. They are perfectly hardy native plants of great use in shrubberies and for covering waste places. They bloom with the equally useful but more graceful and pretty *V. acerifolium* near the middle of June. The last species of Viburnum to blossom is *V. molle*, a plant of generally southern habitat, but which is also found on Nantucket Island, the mildest spot in Massachusetts. It is quite hardy. In foliage, flower and general appearance it closely resembles *V. dentatum*, which under the influence of the cool breezes of Cape Ann, only an hour's railroad ride to the north of Boston, blooms a couple of weeks later than it does near this city.

Arnold Arboretum.

J. G. F.

Some American Plants.

Aristolochia tomentosa is a twining and climbing perennial of the same genus as the Pipe-vine or Dutchman's-pipe (*A. Siphon*), and resembles it in many ways. The flowers of *A. Siphon* are larger and a little more showy, but are of about the same shape. The most striking difference is in the size of the

leaf. In *A. tomentosa* they are about five inches long by four broad and somewhat downy. But in the other, though of almost the same shape and shade of green, they are often a foot long by eight inches wide. These large green leaves are so numerous in both plants as to hide both flowers and stems. Both are natives of rich woods in the northern portion of the southern states. They seem to thrive in light or in heavy soils in the sun or shade, and are quite hardy in this latitude.

Adlumia cirrhosa (the Climbing Fumitory) is a delicate climbing biennial, not rare in moist or wet woods. Its foliage and flowers are both very neat, and it is a pity that it is not perennial. When near a bush or something to which it can attach itself it often attains several feet in height, and its drooping panicles of light purple flowers are continuous from June until October. It needs a light soil, and thrives in both sun and shade.

Zygadeus venenosus, from the Pacific coast, has a bulbous root and long grass-like leaves. Its flowering stem is usually a foot or more high, almost naked, and bears at the summit a dense short panicle or head of nearly white flowers a third of an inch wide, and having a yellowish centre. It is perfectly hardy in this climate, and will do well in light or heavy soil in the sun.

Oxalis violacea, the Violet Wood-Sorrel, is one of our prettiest wild flowers at this season. It is sometimes found in southern New England, but is more common southward and westward. It generally grows about six inches high, bearing several large violet flowers nearly an inch wide, which are very showy. It can easily be grown in the shade or in a cool partly shaded situation. A light soil suits it, and if it is to be set in a heavy one peat or leaf-mould should be added.

Brodiaea multiflora and *B. coccinea*, both from the Pacific coast, come into flower at about the same time. Both have bulbous roots about the same size, with long naked stems and grass-like leaves from the bulb. Their stems are each about a foot and a half high, with their flowers in an umbel at the summit. They are often found growing together, and the bulbs are so near alike that collectors frequently get them mixed if taken up when not in flower. But though resembling each other in these points, they are very unlike when in flower. In *B. multiflora* the flowers are upright, half an inch wide, three-fourths of an inch long, and bluish purple in color, borne in a close round umbel and on very short pedicels. The flowers of *B. coccinea*, on the other hand, are drooping, on stems from half an inch to an inch and a quarter long. The flowers themselves are usually an inch or more in length, tubular in shape, and about a third of an inch thick. In color they are deep scarlet for nearly the whole length, or except a short space at the mouth, which is green and white. This last is a very striking plant and valuable for cut flowers. We have the best success with both of these and most other Californian bulbs by setting in autumn and protecting with a covering of leaves. When wintered in a cellar they are inclined to start into growth about the last of February, and this early growth in the cellar weakens the bulbs. They like a fine, well-drained soil and open sunlight.

Brodiaea stellaris is a little, dwarfish species, only four or five inches high, bearing a small umbel of four to six pale blue flowers, with darker stripes. The flowers are a little more than half an inch wide. It is a pretty species, but its stems are too short for cutting.

Brodiaea lactea has almost white flowers, with greenish stripes. The flowers are half an inch wide, in an ample umbel on a naked stem a foot and a half high. Both of these last mentioned should be treated in cultivation like *B. coccinea*.

Tradescantia Virginica, the common Spiderwort, which has been long in cultivation, is a native of moist woods from western New York southward and westward. It is a strong-growing plant, and soon forms dense clumps fifteen to twenty inches high. The flowers are blue, an inch or more wide, with large yellow stamens, which contrast finely with the blue background of the flower. It is easy of culture and is a valuable plant for a shady corner.

Lilium Bolanderi is a rare species from Oregon, growing from six to twelve inches high, with dark red flowers, having darker spots inside. The flower is a little more than an inch long and about as wide. All the specimens I have seen produced only one terminal flower, and the stem is recurved so that the flower is turned downward. It is one of the smallest species and quite pretty. A light loamy soil seems to suit it best.

Allium acuminatum, from the Pacific coast, is usually a low plant, six to eight inches high, with a good-sized umbel of pretty rose-purple flowers. The flowers are half an inch long and about as wide at the opening, on pedicels three-fourths of an inch in length.

Callirrhoe involucrata, the Crimson Callirrhoe, a plant from the sandy plains of Texas, is beginning to bloom. The flowers are sometimes two inches wide and a dark crimson in color. It is a prostrate, spreading perennial, with stems sometimes two feet long. But these long stems, though creeping on the ground, do not themselves take root. The flowers, which are on upright naked stems from four to eight inches long, continue to come all summer. It is perfectly hardy, will do well in light or heavy soil, and is certainly one of our most interesting native plants.

Sedum Nevii is a native of the southern Alleghanies. Its dense leafy stems are usually only two or three inches high,

should be the most valuable on account of the fruit. It is occasionally found in thickets from New England to the Mississippi River, and is more common southward. It needs time to become established, and plants two years old or more have larger and handsomer leaves and fruit.

Southwick, Mass.

F. H. Horsford.

A Few Good Forms of Ficus.

THIS extensive and varied genus contains many species that are both useful and beautiful. It not only includes the common Fig (*Ficus Carica*) and the wonderful Banyan-tree (*F. Indica*), but also a number of our most serviceable stove

The Oldest Locust-tree in Europe.—See page 305.

very even, and form a solid mass of light green foliage, which is very pretty. Its flowering-stem is not so leafy, and rises two or three inches above the rest of the plant, bearing a small three-spiked cyme of white flowers, which much resemble those of *S. ternatum*, but it is fully two weeks later. It is a prettier plant than *S. ternatum*, and can be grown without protection in sun or shade. We have never tried it in a heavy soil.

Dioscorea villosa, the Wild Yam-root, is a twining and climbing herbaceous perennial. Its large handsome leaves are often five inches long by three and a half inches wide, prominently several ribbed, and downy underneath. The flowers are not showy, but the drooping racemes of three-angled pods are very interesting. It is a striking plant, admired by all who are interested in this class, and for shady or half shaded situations is invaluable. It is dioecious, and the female plants

and greenhouse plants. It is almost needless to call attention to the best known species, *Ficus elastica*, its merits as a generally useful decorative plant being so well understood and recognized, and the variegated form of this species has also been commended by various correspondents of GARDEN AND FOREST. Without doubt *Ficus elastica variegata* will take rank among standard decorative plants as soon as the stock becomes so abundant that well grown plants may be procured at a reasonable price.

Another very handsome variegated species is *F. Parcellii*, which has dark green leaves, beautifully marbled and blotched with pure white. It is a plant of good habit and free growth, and quite naturally attracted much attention when first introduced from the South Sea Islands several years ago. This species should have a warm house temperature and a moist

atmosphere, because when allowed to become too dry it is liable to injury from red spider. Among the large-leaved species, *F. macrophylla*, the Moreton Bay Fig is prominent, its large cordate leaves giving quite a tropical effect in the conservatory, and also being very effective for out-door decoration in the summer. It is a strong grower, and soon makes a large specimen.

Ficus dealbata is another notably good large-growing species, and has leaves of somewhat similar shape to those of *F. elastica*, but dark green on the upper side, while the under surface is thickly clothed with pure white tomentum. It was introduced from South America a number of years since, but has not become very common, possibly because it does not root as readily as some other species.

Ficus Porteana also deserves a place among fine foliage plants, having oblong, sharp-pointed leaves from one foot to eighteen inches in length and from four to five inches in breadth, and slightly serrate on the margins. The leaves of this species are not quite so tough and strong as those of *F. elastica*, but they have substance enough to render it very useful for conservatory work. It is a native of the Philippine Islands, and produces its finest foliage when grown in a warm house.

In the scandent section of the Fig family are to be found some of the most useful greenhouse climbers, prominent among which are *F. barbata* and *F. stipulata* (*F. repens*), the first named being much the stronger of the two, and producing dark green, cordate leaves about three inches in length, and more or less clothed with brown hairs. This species, like *F. stipulata*, is especially useful for covering a wall in a warm house, as it adheres very firmly, and, when given congenial treatment, soon covers such a locality with a most pleasing green mantle. *F. stipulata*, and its variety, *Minima*, are not so particular as to locality and treatment, and may be put to a variety of uses besides that referred to above, being readily propagated and of rapid growth.

The various kinds of *Ficus*, in general, are very clean plants and not subject to the attacks of insects, unless much neglected. They are propagated by means of cuttings made from firm wood, many of the sorts rooting best from single eye-cuttings, which should be firmly planted in small pots and tied up to a small stake, so as to prevent them from falling out of the pot on account of the weight of the leaf.

And while they root best in a close frame, yet enough ventilation must be given at night to prevent the accumulation of much moisture on the cuttings, else they are liable to damp off. Sandy loam, slightly enriched with old manure, will be found a satisfactory compost, and with reasonable care handsome plants may soon be obtained.

Crown and Root-Grafts.

I AM glad to see this distinction clearly made by Professor Bailey and others at the Nurserymen's Meeting. Any one who grows his Apple-seedlings for grafting, and grows them well, knows that they will be too long to be used entire, so that the claim often made that trees are grown on "whole roots" is misleading. The roots must be shortened and side-roots removed. The question then remains, whether we shall use any more of each root than the crown section? I have been testing the matter for many years, and carefully noting results. There are elements of great uncertainty in these tests, unless much care is used and sufficient time allowed for observation. Even if the crown is best, crown-cuts are not all equally good; cions are not all equally good; the soil is not always uniform, and other disturbing conditions are possible.

My experience with Apple-seedlings has been that if plump, vigorous seed is used, and properly planted in good and suitable soil, yearling roots are better than older ones. We then have yearling wood in the stock joined to yearling wood in the cion; the size of the stocks is more nearly that of the cions, often allowing the bark to join all around, and the wood of the stock is softer and more easily cut. Two-year stocks are either too large or of inferior growth and quality.

In our climate it has been found a wise plan to plant our grafts deeply, so that but one bud of the cion is above ground—using cions of three buds or more. In this way, from many varieties we can get good roots from above the point of union. When sufficient care is taken in all points I have never seen any marked difference in growth, in nursery or in orchard, between the first and second cuts of well grown and carefully selected roots which could be charged positively to the roots. It must be remembered that we are apt, while at work, to put the larger cions on the top cut, leaving the smaller for the second cut, so that the completed grafts of the latter are some-

what less in size. But, even allowing all that is required here, I am not able to say that alternate rows of first and second cut grafts have ever, in my nursery, shown sufficient difference at the end of the third season to be discriminated with any certainty. So I must conclude that, with good work all around, it is allowable to use the second cut. But with careless work and unsatisfactory material the result might not be the same.

As to the preference for budding over root-grafting, I find many buyers who object to the crook in a budded tree and prefer the straighter root-graft. But aside from this, where iron-clads are demanded, we want none of the stock above ground or near the surface, as must be the case with budded trees.

I can see no reason why trees root-grafted should have roots on one side only. It may happen that an occasional tree will show that peculiarity, but when this occurs so very seldom who can be sure of the cause? I should be most apt to regard it as a peculiarity of the seedling stock. Neither have I noted that the roots of root-grafts are more pronged. Observing nurserymen soon discover that nearly every variety has its own style of root, which is determined by the cion, so that many varieties can, when taken up at three years old, be known by their roots alone. The spadesmen notice this very quickly when digging, and have a ready anathema for certain varieties with a vigorous, deep-going root system.

Newport, Vt.

T. H. Hoskins.

Notes About Blackberries.

KITTATINNY I had thrown out as too tender, although when I did get a good crop it was a very excellent and paying berry. But it did not stay thrown out, so I have adopted the plan of bending the canes over and holding them down in winter with stones or boards. The result is excellent crops on a small scale. The fruit is large and glossy, and good if well ripened. But there must be some of the caution used that was needful in the case of Lawton. It must be well ripened before being picked.

Wachmett Thornless is not thornless, and is not a berry with a single point in its favor for general planting. There may be localities where it is valuable.

Wilson Junior is only an improved Wilson, and very tender indeed. It will come through if covered with snow; but even if bent down and held close to the ground it will kill to the roots during open winters. It is worthless in a northern latitude.

New Rochelle or Lawton is also worthless, except south of New York. Dealers have a habit of calling all improved Blackberries Lawtons. We cannot as yet get any rational distinctions made in this regard.

Taylor is a real acquisition. The size is above medium and the quality very good. The growth is strong and it is among the most productive. It is later than Snyder.

Snyder is a much better and larger berry than was supposed for a long time. Cut the canes back and select a cool, strong soil and it is a prize. On poor soil and where easily affected by dry weather it is too small to be of any value. In quality Snyder is really very good, not sour and not sweet.

Early Cluster and Crystal White, with me, are tender and otherwise valueless.

Erie I hold in the very highest esteem. It has gone through three winters unharmed, and gives a superb crop of very large and very excellent fruit. The color is a peculiar jet black, unlike that of Lawton, with which it has sometimes been confused. I believe a large amount of swindling has been done in sending out Lawton for Erie.

Minnewaski, so far as I have tested it, proves to have all the good qualities claimed for it—a large, handsome and early berry, and a cane not so strong as some, but entirely hardy.

Agawam is another excellent sort, not so large as Erie or Minnewaski, but with me an excellent fruit and a hardy cane. It bears grand crops, and no one is ever cheated by it into biting an acrid berry that he cannot swallow with honest regard for his stomach.

I would select as a list for a home garden Erie, Agawam, Taylor, Minnewaski. Confined to two sorts, I should perhaps take Erie and Agawam; but should not like to miss Taylor.

For market the same list might still hold good, with Snyder added. The Blackberry has been improved far more than is generally known. The Kittatinny caused great disappointment, and led many growers to discard Blackberries entirely from their grounds.

I grow with cultivation for two or three years, but let the plants ultimately take possession of the soil and care for themselves. They do best let alone. Cut out the dead canes, and

cut back the new ones. Weeds and grass will not hold their own with Blackberries in good soil.

The Lucretia Dewberry has been advertised well, and is really a superb fruit; but it must be laid down for winter. The fruit is enormously large, very early and excellent. It can only be grown well by being tied to stakes and bent back to about three feet of iron.

There are two drawbacks to Blackberry culture which seriously mar our pleasure and profit. The first difficulty is with the cruel thorns. Women cannot gather the fruit without having their clothes torn to rags. The rust is another serious trouble. The remedy for this fungus is to cut and burn. I should not try to cultivate any sort that rusted to any extent. With me Kittatinny alone is diseased, and that rarely. This rust is a mischievous malady, and it is not advisable to propagate it. It is not confined to the Blackberry.

The kind of soil for the Blackberry is invariably dry, well drained, strong clay, if possible; but well drained it must be. If I intended to cultivate a plantation I should have the rows ten feet apart and a row of Potatoes between.

E. P. Powell.

Clinton, N. Y.

New Orchids.—A plant of more than ordinary interest is *Odontoglossum hybridum Leroyanum*, the first hybrid *Odontoglossum* raised artificially. Its parents are *O. crispum* and *O. luteo-purpureum*, which were crossed about five years ago by M. Leroy, gardener to Baron E. de Rothschild, in his garden at Amandvilliers, near Paris. The hybrid flowered in May this year, and proves its origin by combining the characters of the two species named. Mr. Sander will shortly publish a figure of it in *Reichenbachia*. Many have obtained seeds, and even seedling *Odontoglossums*, by crossing one species with another, but they have never come to anything.

Odontoglossum Bleu *splendens* is another hybrid, its parents being *O. vexillarium* and *O. Roezlii*. Properly, however, the three should be called Miltonias. This hybrid also originated in Paris, where it was raised by M. Bleu. Its flowers are as large as those of an ordinary *O. vexillarium*, white, tinted with rose, with a crimson blotch at the base of the labellum, and radiating lines of the same color extending a little out toward the margin. It is a curiosity as a true hybrid *Miltonia*, otherwise it is scarcely equal to a good variety of either of its parents. It is in the collection of Mr. F. Sander.

Phajus Henryi appears to be merely a rose colored variety of *P. Humblotii*. Probably the two are the extreme color variations of one variable species. Plants of both were shown in flower by Mr. Sander at the Temple Show. *P. Humblotii* is likely to prove a good garden Orchid, as it grows freely and flowers well.

Kew.

W.

Sagittaria Chinensis was received from a Chinese laundryman early in the year as an egg-shaped, whitish tuber with a short sprout. It was planted in a bowl of earth and kept saturated with water, and proved a very rapid grower and attractive plant a foot high, with light green foliage and the many arrow head leaves rather broad. Removal to an outside tank has checked its growth and flowering so that it is not possible to say whether or not it is *S. Latifolius*, the only Chinese species which can be found in catalogues. Special interest was excited in this plant from a hope of discovering that our Chinese friends, with their materialistic reputation, were not without some of that sentiment which has led emigrants in all ages to take with them some favorite plants as a reminder of their birthplace. We are already indebted to them for the Water Narcissus or "Sacred Water Lily," apparently first brought here without hope of gain, and it seemed as if the *Sagittaria* might be an introduction of another favorite home plant. This theory I regret not being able to verify, as my interviews with growers of the plant in the Chinese colony simply proved that they grow the plant, but with no great enthusiasm, such as they evidently feel about the "Sacred Lily." A Chinaman is not usually an open hearted enthusiast, but I found a number of them in humble quarters become bright-eyed and vivacious over the Narcissus. Lately the street fakirs have offered dormant tubers *Sagittaria*, but of what variety is unknown to me.

Tulipa ciliatula.—This is the name I find given by Mr. J. G. Baker to a new Tulip which he describes in the *Gardeners' Chronicle* for May 24th. I received it directly from Mr. Whitall, who collected it on the Anti-Taurus Range in Asia Minor, and sent it out last year. With me it came into bloom in the open border in April. It is nearly allied to *T. Gesneriana*, with the same bright crimson-scarlet petals, and glaucous, undulated foliage. It is of very dwarf habit, the peduncles being only two

inches long, and is an excellent plant for bright bedding or for the rockery.

Oenothera Fraseri is one of the best of the Evening Primroses. The flowers are light golden yellow, borne profusely on a dwarf plant a foot high, which remains in bloom for several months. It is a native plant long in cultivation. The fields are now bright with *Oenothera biennis* and Dog Roses, and it may be noted that for a bright bouquet there are few more pleasing combinations than these two flowers, loosely arranged.

Iris lævigata opened its first bloom on the 15th of June, on the borders of the pond, where they seem to be about a fortnight earlier than in a dry and somewhat shaded border. There are handsomer flowers among the Irises than Kämpfer's, but these have a quaintness and a grace of their own. The varieties with dark reticulations are specially quaint, and good white forms are very pleasing. It is interesting to grow this plant from seed, as it comes into bloom in two and three years.

Elizabeth, N. J.

G.

A Good "Cutting" Lettuce.—The French works on gardening describe a class of so-called "cutting Lettuces," of which a distinguishing characteristic is that if the leaves are plucked from the plant one by one others will develop to take their places, and thus a single planting will continue to furnish a crop of leaves through nearly the whole season. I have tested these Lettuces and found none of them to be of the finest quality, all being too bitter to suit our American taste. It may not be generally known, however, that some of our best common Lettuces, when given good soil and culture, will furnish several successive crops of foliage without running to seed, if the leaves are picked off one at a time, and are not drawn upon too largely. I have grown the Prize Head Lettuce in this way during the past two seasons with excellent results. A bed covering a few square feet furnishes sufficient lettuce for daily use during several successive weeks.

Correspondence.

Appropriate Bridges.

To the Editor of GARDEN AND FOREST:

Sir.—You can do no better work, I think, by means of the charming illustrations you publish, than to continue to show American readers what good rural bridges should look like. There is a growing desire in this country to build substantial bridges and to make them beautiful as well as solid. But often there seems no realization of the fact that beauty means appropriateness, or, at least, no true feeling for what is appropriate and inappropriate. For example, while passing through Connecticut by rail the other day, I noticed in one of the smaller towns (was it in Milford?) a small stone bridge, spanning a stream close to the railroad, which seemed to have been recently built. Although neither long nor high and placed in a modern town of modest aspect, where most of the neighboring buildings were of wood, this bridge has crenellated sides, and, at one end, a circular turret, whose top, as I remember, was similarly protected against impossible enemies. In itself it was not beautiful, looking sadly like the *papier-maché* fortifications of the scene-painter. And could anything more inappropriate be imagined in a New England town of to-day than a battlemented bridge, suggesting the conditions under which people lived in other lands in mediæval times? Of course, the cost of such a structure must have been much greater than that of a simpler stone bridge, and every penny of the difference had been worse than wasted, producing a thing which was not beautiful in itself, and which looked still less so by contrast with its surroundings.

The Paragon Chestnut and The Crandall Currant.

To the Editor of GARDEN AND FOREST:

Sir.—Referring to your report of the Nurserymen's Convention, page 292, allow me to enquire (1) whether the Paragon Chestnut was not propagated from grafts furnished by my late neighbor, Mr. W. L. Shaffer.

Mr. Shaffer's tree was from a Spanish Chestnut.

(2) Again, what is the difference between the Crandall Currant and the Utah Black and Utah Yellow Missouri Currants, which have been under cultivation for twenty-five years, and were originally distributed by Siler, Reading and others?

Germanstown.

Thomas Meehan.

[1. Perhaps Mr. Van Deman was incorrectly quoted as saying that the Paragon Chestnut is of "purely native origin."

In the Report of the Secretary of Agriculture, just issued, he says: "It is possible that this variety may have some foreign stock in it, as the leaves differ slightly from those of our native species." Mr. Engle received the grafts from Mr. Shaffer under the name of Great American, and he changed it to Paragon because he feared the first might be misleading. He knew nothing of its origin, but supposed it might be a cross between our native Chestnut and some foreign variety, since the flavor is nearly equal to that of our own Chestnuts, while the nut is as large as the foreign sorts. We should be glad to have further information as to the parent tree. A good illustration of the nut appears in the report of Mr. Van Deman.

(2) Professor Bailey, who has recommended the Crandall Currant highly, is not acquainted with the Utah Currants spoken of, although he has heard of them. Mr. A. S. Fuller commends these Utah forms in his "Small Fruit Cultivist;" but he is unacquainted with the Crandall. We should be obliged for a report on the comparative value of the Crandall and these older introductions from any one who has tried both.—Ed.]

The American Association of Nurserymen.

Fifteenth Annual Meeting.—III.

THE papers which follow conclude our report of the late Convention of Nurserymen in this city. The next Annual Meeting will be held either in Minneapolis or St. Paul, as may seem best to the Executive Committee.

THE CULTIVATION OF THE CHESTNUT.

Mr. Samuel C. Moon read the following paper on this subject:

Chestnut culture in orchards is a young industry in this country, and although it has already been proved to be profitable, the subject is as yet imperfectly understood. The Chestnut-tree is widely distributed throughout the country, and yet there are large districts in which it is not found, and the question is often asked whether it will grow on bottom lands or on limestone lands? I cannot reply to these questions, and would be glad if some experiment station would investigate this subject. In Arthur Bryant's book on forest-trees it is said that "the Chestnut seems to prefer the sides and neighborhood of hills and mountains with a dry sandy or gravelly soil, although it will grow on almost any soil except a wet one. It does not appear, however, to grow more rapidly in the rich soils than on the poorer lands. Lands utterly worthless for cultivation may be made to yield an income by planting them with Chestnuts."

No trees which are equally well adapted for avenues will yield any return like our native nut-bearing trees, and none are more appropriate for shade and ornament about buildings or along farm lanes or in pasture fields. In planting the Chestnut, whether in orchards or avenues, the trees should be set at least forty feet apart, and some varieties will need forty-five or fifty feet. Like other fruit-trees, they should be mulched, or the land should be kept mellow about them while they are small, and they will come into bearing as soon as Apple-trees or Pear-trees. Wild trees usually commence bearing when from twelve to twenty years old, and grafted ones of the most productive varieties from two to seven years after grafting. A Chestnut-orchard of the Numbo or Paragon varieties will come into bearing condition as soon as an orchard of Baldwin Apples. Both of these varieties possess the qualities which make any orchard-fruit profitable—that is, hardness of the tree and early fruitfulness, with large size and fine appearance of fruit.

Efforts to introduce the Maron de Lyon and other large European varieties have not been successful, for although the trees may live a few years, they ultimately die. Trees imported from Europe, and trees grown here from imported seed, are not generally hardy; but stock raised from the seed of the exceptionally hardy European trees that do flourish here have proved hardy themselves, and in this way a strain of European Chestnuts has been secured which will endure the climate of the eastern states. Many individual native trees in different parts of the country have local reputation for superiority, and are no doubt worthy of dissemination, but they have never been introduced, and, like other new fruits, will need to be tested in different sections and under varied conditions before they can be confidently recommended. As the demand for new and improved varieties develops there is

little doubt but that superior kinds will be found and disseminated.

In habit of growth the American Chestnut differs from the European about as the Sugar Maple differs from the Norway Maple. The foreign Chestnut branches low and forms a round-headed tree, while the native variety grows taller and more spreading. The Japan Chestnut seems to be smaller than either of the others, with smaller foliage, and its slender, compact habit makes it an acquisition for small plantations. None of the large Chestnuts, and no foreign Chestnut that I have seen, equals in flavor the small ones on our native trees when they are eaten uncooked. They lack the sweet and delicate taste with which we are familiar, and there is an astringency in the skin which covers the kernel, but boiling or roasting corrects this unpleasantness, and after being cooked there is little difference in the taste of the foreign varieties and our own. When the culinary uses of Chestnuts are appreciated here as they are in Europe, where the cooks prepare them in a variety of ways, the demand for those of large size will rapidly increase.

I find the Chestnut an expensive tree to raise, and this cost of production is an obstacle in the way of its general cultivation. I have found difficulty in grafting the trees and loss in transplanting them. It has not paid to graft them until after they are once or twice transplanted and when the stocks are three, or, better yet, five years old. My most successful take of grafts yielded seventy-five per cent. of saleable trees, but I have more frequently had seventy-five per cent. of failure. I have tried taking up one year's seedlings and grafting at the collar as Apples are worked, on whole roots. I have tried collar-grafting of one-year-old seedlings as they stood in the nursery row, using ordinary tongue-grafts, but with no success. I have failed also entirely with ordinary budding. I have been most successful when I cut the cions early in spring and kept them dormant in an ice house until the stocks started and the buds on them were well swollen. My practice then is to cut off the tops and insert tongue grafts wrapped in waxed muslin in the ordinary way. In some cases the grafts do not unite well and there is no perfect union between stock and cion. Such trees, of course, are short lived and worthless. This defect is more common with some varieties than others. I have one valuable variety that I have never yet succeeded in grafting. Three years ago I headed in a large European Chestnut tree with fifty grafts of the Japanese variety and every one took and looked well. This year, however, I found the unions all imperfect and they will evidently soon decline.

The difficulty of successful transplanting seems to lie in the extreme sensitiveness of the roots to exposure and their slowness in re-establishing themselves in the soil. If the roots get at all dry the vitality of the tree is wasted by evaporation before they become sufficiently established to supply the demand upon them. I therefore dig and handle Chestnut-trees on damp and drizzling days and puddle the roots as soon as they are dug. These difficulties are annoying but I do not consider the obstacles insurmountable. What is needed is extra care in every part of the work of handling the trees, from the time the seeds are sown until the grafted trees are set in their permanent positions, and I believe that after intelligent effort and experiments have been made by a large number of practical nurserymen in this direction, means will be found by which the trees can be produced as rapidly and cheaply as they are needed.

In the discussion which followed it was explained by Mr. Fernow that the Chestnut is not so particular about the chemical composition of the soil as about its mechanical condition. Where the Chestnut does not thrive on limestone land it is because the solid rock not far below the surface obstructs drainage. In limestone lands where there is an open, permeable subsoil the Chestnut flourishes. The same causes sometimes exclude the tree from alluvial bottom lands. To attain the best growth it needs deep, free and open drainage.

HARDY PERENNIALS.

Mr. J. W. Manning, Jr., of Reading, Massachusetts, read a paper on the question whether it is desirable for nurserymen to include hardy herbaceous plants with the trees and shrubs to which their business in this country is generally confined. Mr. Manning replied by saying that a few years ago there was little to encourage nurserymen to cultivate this class of plants; but that a great change had taken place in the character of the material used for ornamental planting. Old-fashioned plants which gave abundant flowers from spring till autumn in a succession of bloom were again coming into favor. They had been for some years removed to the background, and their places had been occupied by stiff arrangements of bedding

plants. These plants were expensive to keep through the winter, and required great care, and produced, after all, an effect which covered but a few months in the year, leaving the spring and autumn garden bare and empty. The return to a more natural style has brought into prominence these hardy plants, many of which are quite as brilliant in foliage as the bedding plants which they are replacing. We are by no means confined, however, to plants which flourish in old-fashioned gardens, for an increased knowledge has brought into cultivation hundreds of beautiful plants from all the temperate and mountainous regions of the globe until there is abundant material for beautiful floral effects, from the earliest spring until freezing weather, to be had with these hardy herbaceous plants, and while an ample variety of foliage and flower can be secured to suit every soil and situation and individual taste, less care and expense is required to cultivate them than is needed with the artificial bedding system.

The use of these perennials is not confined to the flower border alone; many of them are adapted for use on edges of shrubberies and in half wild situations so that large parks and public gardens can hardly be treated with proper landscape effect without using them in great abundance. It would be hard to treat rocky ledges, or shady nooks, or swampy lands, or the banks of ponds or streams without them.

Nurserymen were advised to begin at first with those that are most easily cultivated and propagated, avoiding weedy kinds and including in the main such as are of medium size and a long flowering season and having abundant bloom. A few of the taller kinds are indispensable for large effects, and a few of the exceedingly dwarf kinds are equally indispensable where a low creeping growth is needed. As a whole, no class of plants is more easily multiplied, and the only propagating apparatus needed is that found in the ordinary nursery business. They take up little room, and a large variety can be cultivated on a small area, so that the filling of orders is easily accomplished, and the work of digging and packing is a small item.

Mr. Manning concluded with a list of the hardy plants which were in greatest demand, but we omit it, as we give so much attention to this class of plants from week to week.

Periodical Literature.

IN the fourth of his "Artist's Letters from Japan," published in the June number of the *Century Magazine*, Mr. La Farge speaks more particularly about architecture and gardening. His chief text is the temple of Iyémitsu, which, like the more pretentious one of his grandfather, Iyeyasu, stands on the sacred mountain of Nikko. The purely architectural descriptions, marked naturally by the keenest artistic feeling for effects of light and shadow as well as for form and color in themselves, do not here concern us as much as those which show how inevitable in the Japanese mind nature and art are treated as a single entity, and to produce beauty means to blend the work of man in the most subtle ways with the work of God. The temple in question, says Mr. La Farge, is "fitted into the shape of the mountain, like jewels into a setting. From near the red pagoda of Iyeyasu's grounds a wide avenue leads, all in shade, to an opening, narrowed up at its end to a wall and gate, which merely seems a natural entrance between the hills. There are great walls to the avenue which are embankments of the mountain, from which at intervals fountains splash into the torrents at each side, and overhead are the great trees and their thin vault of blue shade. The first gate is the usual roofed one, red, with gilded rafters and heavy black-bronze tiles, and with two red muscular giants in the niches at the sides. Its relative simplicity accentuates the loveliness of the first long court, which we enter on its narrowest side. Its borders seem natural, made of nothing but the steep mountain-sides, filled with varieties of leafage and the columns of the great Cedars. These indeterminate edges give it the look of a valley shut at each end by the gate we have passed and by another far off disguised by trees. This dell is paved in part and with hidden care laid out with smaller trees." A cascade falling from the hill fills a large stone tank and "the little pavilion over this well is the only building in the enclosure. . . . As we turn to the highest side of the court on the left and ascend slowly steep, high steps to a gorgeous red gate above our heads, whose base we cannot see, the great Cedars of the opposite side are the real monuments, and the little water-tank upon which we now look down seems nothing but a little altar at the foot of the mountain forest. The gate, when we look back, is only a frame, and its upper step only a balcony from which to look at the high picture of trees in

shadow and sunlight across the narrow dell, which we can only just feel beneath us. . . . Just behind the gate, as if it lead to nothing, rises again the wall of the mountain; then we turn at right angles toward a great esplanade, lost at its edges in trees, from which again the forest would be all the picture were it not that further back upon the hill rises a high wall with a platform and lofty steps, and the carved red and gold frame of a cloister with another still richer gate of red lacquer, whose suffering by time has made it more rosy, more flower-like." This is but the beginning of Mr. La Farge's description of this shrine and its enclosures, but it is enough to show how nature and art intermingle, interpenetrate each other under the hand of the Japanese artist. More and more this impression is strengthened as further steps are taken through the varied enclosure, until we reach "the distant steps leading through the trees to the tomb. . . . surrounded by the still more solitary splendor of the forest," its bronze and lacquer and golden carvings contrasting with wild rocks and trees, grasses and mosses, and, when the winter shall come, standing unprotected amid the snow and storms. Such a scene, as the writer says, brings a feeling of humility and of the nothingness of man." It is as if these tombs said, "serenely or splendidly, in color, and carving, and bronze, and gold: 'We are the end of the limits of human endeavor. Beyond us begins the other world, and we, indeed, shall surely pass away, but thou remainest, O Eternal Beauty.'"

With humbler buildings the effect is the same—their surroundings form part and parcel of the design and it is impossible to say where nature ends and art begins. "What is natural," says Mr. La Farge, "and what was made by man has become so blended together, or has always been so, that I can choose to look at it as my mood may be, and feel the repose of nature or enjoy the disposing choice of art." Simplicity is the note of gardening art—small gardens needing few hands to keep them in order. Yet order means something much more artistic and particular than with us. Each day in the small garden near the writer's lodging "the gardener appears and attends to one thing after another, even climbing up into the old Pine-tree, taking care of it as he does of the Sweet Peas; and I recall the Japanese gardener whom I knew at our Exposition of 1876, as I saw him for the last time stretched on the ground fanning the opening leaves of some plant that gave him anxiety." It is pleasant to find that the estimate of the Japanese point of view as regards miniature gardens, which has more than once been theoretically explained in these columns, is here echoed by a keen observer who has made practical acquaintance with them and their creators.

The Japanese miniature garden, he says, "can be made of very slight materials, and is occasionally reduced to scarcely anything, even to a little sand and a few stones laid out according to a definite ideal of meaning. A reference to Nature, a recall of the general principles of all landscapes—of a foreground, a distance and a middle distance—that is to say, a little picture—is enough. When they cannot deal with the thing itself—when they can they do it consummately—they have another ideal, which is not so much the making of a real thing as the making of a picture of it. Hence the scale can be diminished without detriment in their eyes until it becomes Lilliputian to ours. All this I take to be an inheritance from China, modified toward simplicity." Mr. La Farge also notes that these little gardens cannot be appreciated by us as they are by the Japanese, "for they have in their arrangement manners of expressing ideas of association, drawing them from nature itself or bringing them out by references to tradition or history, so that I am told they aim to express delicate meanings that a Western imagination can hardly grasp; types, for instance, conveying the ideas of peace and chastity, quiet old age, connubial happiness and the sweetness of solitude. Does this make you laugh, or does it touch you—or both? I wish I knew more about it, for I am sure there is much to say." But, as the writer confesses, there are many points with regard to the artistic ideals of the Japanese where a foreigner cannot inform himself, whether it be because the full import is lost in the mists of antiquity, or because "they reserve it for better minds and worthier apprehensions." The most significant fact made plain in this delightful chapter of Mr. La Farge's is, we repeat, that architecture is not an isolated art, but one intimately involved with the love of nature and with the power of treating it in artistic yet naturalistic ways. A temple is not what we would understand by the name, but is a number of buildings of various kinds "spread with infinite art over large spaces, open or enclosed by trees and rocks. The buildings are but parts of a whole. They are enveloped by Nature, the principle and the adornment of the subtle or mysterious meaning which links them all together."

Notes.

Peaches, green apples, blackberries and huckleberries are coming into market from the Carolinas, and the first Wild Goose plums from California.

It is stated in *The Agitator*, published in Wellsboro, Tioga County, Pennsylvania, that a giant Hemlock was recently felled in Union Township, of that county, from which forty-nine four-foot lengths of bark were peeled.

The last part of *Hooker's Icones Plantarum* (xxi., Part 1) to reach us contains plates 2007 to 2025 inclusive, and is entirely devoted to the illustration and description of Indian Orchids of various genera, none of them of ornamental or horticultural importance.

Lonicera fragrantissima, which the past mild season brought into bloom in January in this vicinity, is named in an Austrian journal as a true winter-blooming species, the flowers of which are as fragrant during the snowy months as those of other Honeysuckles in summer.

A bark laden with 580 sticks of spar-timber from Oregon recently arrived in Boston. The cargo was valued at \$150,000, and a portion of it was at once purchased by a shipbuilder of Bath, Maine—a fact which shows how grievously the Maine forests have been denuded of their finest products.

A correspondent in eastern Massachusetts informs us that the Sycamore-trees in that region are all suffering from the disease described in our issue of last week; and that it is many years since they have been in such a deplorable condition as they are at present, although years ago they suffered to almost the same extent from apparently the same cause.

The *California Fruit-Grower* contains a colored plate of the new Rose, Rainbow, which was originated by John Sievers, of San Francisco. It is a sport from Papa Gontier. It is a pink rose splashed with the deeper color of Papa Gontier. It is said to be larger, firmer and more fragrant than its parent, and, besides being more productive, it is superior in its forcing qualities.

Le Journal des Orchidees, of which the sixth issue has now reached us, more than sustains the promise of the earlier numbers. It contains a large amount of practical instruction about Orchids and their cultivation of a character which amateur growers of these plants find most difficult to obtain, and which is conveyed through its columns in a plain and most satisfactory manner.

An ingenious berry-picking box is described by a writer in the *Orange Judd Farmer* as in use on a fruit farm in Wisconsin. It consists of a tin box just large enough to hold the quart box in which berries are sent to market. The lid is hinged, and in its centre is a small funnel through which the berries are slipped without injury or loss. A strap attached to the box fastens it to the body, leaving both the picker's hands free.

Just as this paper is ready for the press comes the sad announcement of the death of Patrick Barry, of the firm of Ellwanger & Barry, Rochester, New York. Occasion will be taken later to give some account of his eminent services to pomology and horticulture, but we cannot forbear in the moment we have at command to express our feeling of bereavement at the loss of this broad-minded and public-spirited man.

Mr. Alma-Tadema is known to pride himself almost as much upon the archæological accuracy as upon the beauty of his pictures of ancient Roman life. It is no wonder, therefore, that English journals are making merry over the fact that he recently introduced into one of them a representation of *Clematis Jackmanni*, as this now familiar plant is a hybrid variety produced about thirty years ago by Mr. C. Jackmann, of Woking, in Surrey.

The Ninth Annual Meeting of the American Forestry Association will be held in Quebec from the 2d to the 5th of September. All those who attend the meeting should procure receipts from the ticket-agents at the point of departure. Reduced return fares can be secured over roads connected with the Trunk-line Association, provided at least fifty receipts are presented at the meeting for endorsement. Further information can be obtained from Dr. H. M. Fisher, 919 Walnut Street, Philadelphia.

A machine for budding has been invented by Mr. W. M. Rowell, a young man living in Fort Meade, Florida. Mr. Rowell's budder, being "loaded" with a bud, plows under the bark, a pull on the trigger drives the bud in, and it is left in

proper position for binding. Mr. Rowell claims that 12,000 buds can be inserted in a day with his budder and that a child can learn the use of it in fifteen minutes. This implement is in some respects like a seed-dropper. The part that holds and inserts the bud is made of different sizes or numbers, adapted to different sizes of buds and stocks. By changing the points it may be used on stocks ranging from an inch down to nearly one-eighth of an inch in diameter.

Mr. C. R. Orcutt writes that the manufacture of syrup from the fruit of the *Opuntia* may at no far distant day become an important industry in southern California. *Opuntia Ficus-Indica*, or Indian Fig, *O. Tuna* and *O. Tuna-manse* have become naturalized around the old Californian missions. They are natives of Mexico and make rank and rapid growth. The juice of the fruit, which these plants produce in great abundance, may be extracted in a cider press like the juice from apples, and boiled down to a fruity syrup indistinguishable from that manufactured from the watermelon. Excellent vinegar may also be made from the juice. In Mexico these Cacti are extensively cultivated for their fruit.

So few places in the Central Park are disfigured by inappropriately placed formal flower-beds that the one near the Mineral Spring, to the north of the large sheep-meadow, is a surprising sight. A long, low rock lies here, beyond a narrow stretch of lawn, partly covered with Virginia Creeper and other vines and overhung by tall Sumachs, a Chestnut of shrub-like habit, and a Wild Cherry. No rock on the borders of a New England pasture could look more natural, yet close in front of it, following its outline, now lies a great bed set with Scarlet Geraniums, Coleus and Vincas, arranged in formal patterns. Fortunately, it is invisible except to those who pass along the somewhat unfrequented path, and one can only hope that it is not a prophecy of more numerous errors to come.

At the recent great horticultural exhibition in Berlin the prize for the finest Orchid grown in Germany was given to Herr Bouche, of Endenich, for a plant of *Cymbidium Lowianum*. But it is said that his success was owing to the rapid fading of a *Phajus tuberosus* exhibited by Herr Lackner, of Steglitz. This species had bloomed but three times before in England, and never on the Continent, and the plant in question was greatly admired in the brief period during which its flowers remained in good condition. One of the most remarkable exhibits was a collection of 250 species of Cactus shown by Herr Gruson, an amateur of Magdeburg-Buckau, which received the "prize of honor," a large silver medal given by the state. There were 634 exhibitors in the different departments of the display.

We learn from the *Pacific Rural Press* that the state of California has received from Mr. Abbot Kinney, of Lamanda Park, a donation of many thousand young forest-trees, reared at that gentleman's expense. In making this presentation he has selected the State Board of Forestry as the proper channel for the direction of them to the best uses. Such of these trees as are not required to perfect their own plantations will be distributed during the coming season to such applicants as will conform to the Board's request to furnish the customary reports as to locality planted, growth made, conditions observed, etc. In selecting the State Board as the medium for the dissemination of these trees, Mr. Kinney was doubtless influenced by the knowledge that the intelligent direction of the chairman of the Board, Hon. Walter S. Moore, to promote the cause of forest-planting would be fully exercised to insure such disposition of this gift as would result in the greatest benefit to the people of the whole state.

A few weeks ago one of the most interesting old houses in New York State was destroyed by fire. This was the Hogeboom homestead, at Claverack, near Hudson, known to recent generations as the "Watson Webb House." It was built by Jacobus Hogeboom in 1727 on a tract of land which his father, Kiliaen, had purchased from Chancellor Livingston. Its façade measured sixty-three feet and was adorned by a deep porch, while an immense Ivy had nearly covered both porch and wall. The interior was treated in the characteristic Dutch way, with carved and tiled mantels, and, it is said, mural paintings. Before the Revolutionary War broke out the house had come into the possession of General Watson Webb, who had married a grand-daughter of its founder. During a visit made by Lafayette he scratched his name and the date on a window-pane, which, of course, was thereafter guarded as a precious relic. And every child in America should regret the destruction of the mansion, since under its roof Moore wrote "Twas the night before Christmas."

GARDEN AND FOREST.

PUBLISHED WEEKLY BY
THE GARDEN AND FOREST PUBLISHING CO.
OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, JULY 2, 1890.

TABLE OF CONTENTS.

	PAGE.
EDITORIAL ARTICLES:—Horticultural Education.—Preserving Natural Scenery.—	
The Growing Scarcity of Lumber.....	317

The Carob-Tree (Ceratonia Siliqua).....	323

Horticultural Education.

A CORRESPONDENT referring to Professor Bailey's article upon the value of horticultural education, desires to be informed just what is meant by that phrase. It may be answered in a general way that one could appropriately be called educated in horticulture when he had an adequate schooling in the accepted theories of horticulture or in the sciences related to horticulture as distinguished from a mere familiarity with the practice or art of horticulture. Of course it is not expected that a young graduate will be an expert in chemistry, botany, entomology and all the other sciences which furnish explanations for the best garden practice, but he should have a rudimentary knowledge that will enable him to understand what explorers in each of these fields are looking for and finding, and to apply these discoveries to his daily practice. Above all, he should have the broadened intelligence, the more cautious and accurate judgment and the more alert and fruitful imagination which scientific training brings.

Now there is no specific course of instruction which would be the best for all who purpose to devote themselves to horticulture. The best training would vary according to the mental bias and capacity of the student, the particular branch of horticulture he wished to prosecute, and so on. It will be set down as established, however, that a fair general education is the best possible foundation for any special training. The course of agriculture in Cornell University, as we have learned from Professor Bailey, is based upon this idea. The two years of general training are meant to establish habits of study and direction of thought. They embrace a thorough training in English, with instruction in French or German or both, mathematics, elementary chemistry and botany, zoology, entomology, physiology and hygiene, physics, free-hand drawing and logic. Upon completion of the second year the student is allowed to make selections from optional studies. If he takes a course in general farming he selects studies

in that direction, or he may choose agriculture, chemistry, economic entomology, veterinary science and practice. He may also select studies from the purely scientific and literary course, but at least three-fourths of the work in the last two years must be devoted to subjects directly relating to agriculture.

If he selects horticulture as an optional study he pursues the study of botany in considerable detail, and he is then afforded the following courses:

1. Variation of Plants under Culture. A discussion of the principles which underlie the modification and amelioration of plants under the hand of man. The course includes the consideration of acclimatization, the modification of plants by latitude and climate, pollination and hybridization, selection, influences of soils and treatments, histories of cultivated plants, etc. Lectures.
- Course 1 is open to all students in all courses who have taken Systematic Botany.
2. Olericulture, or Vegetable Gardening; including also a full discussion of forcing and forcing structures. Lectures and other class work. Laboratory work.
3. Pomology. Lectures and other class work. Practicums once a week.
4. Handicraft. Practical training for students who intend to follow gardening as a business. An extension of either Course 2 or 3, or both.
5. Investigation incident to previous courses. For graduates and advanced students.

The last two courses are flexible and adapted to the convenience of both professor and student, and they allow one to take up advanced studies in the particular directions of proposed work. The students in these courses are few, but it is here that the skill of the teacher is best shown, and special adaptability of the student more plainly appears. Here the teaching is not didactic; teacher and student work hand in hand. Students in these advanced courses become more than mere graduates. Just now three young men are taking under the last course a special training in crossing and hybridizing, which is extended through several months.

In connection with all the courses general reading on the various subjects discussed is required and examinations are held upon books which have never appeared in the class room. Actual practice is exacted in connection with all technical courses, and excursions are taken to good orchards, nurseries and gardens in various parts of the country. Besides the above courses similar ones are afforded in arboriculture and landscape-gardening, and the practical work is aided by the use of the orchards, the vegetable-gardens, ornamental grounds, forcing houses and greenhouses connected with the University.

No college course extending over two or three years will suffice for the training and equipment of a first-rate gardener, but any young man would surely be better prepared for gardening with such a schooling than without it. With it, he would at least be less opinionated, more ready to be taught, more alert to discover improved methods of practice, and more prompt to adopt them; he would be at once more modest and more truly self-reliant.

THE movement for the establishment of a State Board of Trustees empowered to acquire and hold for public use and enjoyment historic sites, tracts of interesting scenery and open spaces of any desirable kind, which was recently started in Massachusetts by the Appalachian Mountain Club, ought to have far-reaching results. Any such exhibition of interest in the preservation of natural scenery is encouraging, as evincing capacity for pleasures which are in no degree sordid or material, and as indicating, perhaps, a slight gain in the higher elements of life and civilization. The wish to do what is thus proposed is, no doubt, a natural result of the out-of-door activities of the Club. It has been awakened in the minds of the members by personal contact with nature, and by their familiarity with interesting and beautiful scenery. It will probably be found

easier to inspire interest in the acquisition of historic sites than in the other objects of the undertaking. This part of the enterprise will come nearest taking care of itself.

The popular interest in the preservation of scenery, and the popular appreciation of the value of opportunities for change of scene and for contact with unspoiled natural beauty and calm, are but slight, but they admit of cultivation and development. An increasing and enormous density of population is certain, within a few decades, to develop conditions of life in all our older states which only thoughtful men and women now foresee. Our country is rapidly becoming a land of cities and towns. As people are, more and more, obliged to live and work in thronged and crowded communities, the need of occasional escape from the pressure of toil, and of recreation, by experience of the silent unconcern of nature, becomes more imperative. The most important among the objects of this movement is the acquisition of open spaces, places where the people of the towns can breathe, and the establishment of conditions under which they will be permanently available for public use. Their management and embellishment can be considered afterward. They will reflect the taste and civilization of the people of the state. But it is always appropriate to say that in such places we do not want statues or fine buildings or decorative artificial gardening. All these are impertinences, but trees and grass, rocks and streams,

"The wide, aerial landscape spread,"

the open air, the sky and sea—these have the power to heal and soothe and charm.

The movement should be made broad enough from the beginning to include and enlist all who appreciate out-of-door interests and objects of any kind, the preservation of natural scenery, the care of trees, forests and wooded lands, and of fish and game preserves, the purity of the water-supply for cities and towns, the treatment of roadsides, and of mountain and sea-shore commons and public parks and open spaces. The development and direction of popular interest in the objects of the undertaking will require and reward persistent effort. The work has been very happily begun, and all public-spirited citizens of the commonwealth should help to make it successful.

The North-western Lumberman, a trade journal published in Chicago, has for years been endeavoring to turn into ridicule every statement which has been made with regard to a probable failure of the pine supply of the north-west. To our enterprising contemporary the forests of the lake region were boundless and inexhaustible, and the men who ventured to suggest that even an American forest, if a hundred times as much lumber was cut from it every year as the annual increase of the trees produced, must in time come to the end of its productive powers, were set down as cranks or alarmists, or something worse. It is interesting, therefore, and exceedingly suggestive, to find in a recent issue the following statements:

The most conspicuous feature of the present season's lumber trade in the north-west is the comparative scarcity of what, in this market, is called good lumber—that is, lumber that will grade C and better. Not two years ago selects and uppers were the druggiest lumber going, stocks in this market having been large, so that dealers made sacrifices of price to get rid of such stock.

A decided change has come in respect to good lumber. Men who two years ago scouted it as a drug cannot now obtain it without special effort. Time was when dealers expected to get a fair proportion of good lumber with the inferior grades, and that without difficulty in the open market. Now they have to go on a still hunt for good stock. The fact is that good lumber is getting scarce, and dealers who want to handle it are put to their wits' end to procure it in sufficient quantity unless they choose to bull the market in competition with other buyers.

The result of this more recent development in the trade is to reduce the average quality of stocks that are thrown on the open market. There is plenty of coarse lumber, and the tendency is to a constantly overloaded market for such product.

The Carob Tree.

THE illustration on page 323 represents a specimen of the Carob-tree or Carubier of the French—the *Ceratonia Siliqua* of botanists—taken in Algeria. The Carob is a widely distributed plant of the Mediterranean Basin from Spain to the Orient, but more especially of northern Africa, where it grows in all sorts of soils and situations from the slopes of the driest limestone mountains to the most fertile oases. It is not common, however, even in Algeria or in Tunis, and grows as an isolated specimen, or in groups composed of a few individuals. The Carob is one of the most beautiful and useful trees of the countries which it inhabits. It grows to the height of forty or fifty feet, with a stout trunk, and a compact head of dark green, lustrous evergreen foliage. The flowers are not at all conspicuous or showy, resembling somewhat in size and arrangement those of our Three-thorned Acacias, to which the Carob is rather closely related botanically. The fruit is a thickly curved pod, and when it is ripe the seeds are encased in a sweet pulp, which is eaten by the people of the countries where the tree is found. The great value of the fruit of this tree, however, is to feed to horses and hogs, which fatten on them rapidly; and great quantities of Carob-pods are exported from Crete and other eastern countries to central and northern Europe, especially to Great Britain, for this purpose. The pulp has been found to contain sixty-six per cent. of pure sugar and gum, and it has been used in the manufacture of syrups, liquors, and an imitation of chocolate, and by the Egyptians in preparing a sort of sugar used by the Arabs; the pods, too, are preserved in the same manner that the pods of the Tamarind are preserved in India and other tropical countries.

There is considerable historical interest attached to the Carob; the fruit was once supposed to be the food which supported Saint John in the wilderness, the seeds being held to mean "locusts," and the pulp "wild honey," so the tree or its fruit came to be called "St. John's Bread;" and the dry valves of the pods have been considered the husks the Prodigal Son longed for in the last stages of his misery and starvation.

The wood of the Carob is hard, heavy, very durable, and of a handsome rose color. It is admirable furniture-wood, and is used locally for carts and agricultural implements. Its rarity is the only cause which prevents it from being used very generally in construction and the arts.

The Carob, as it flourishes in all sorts of soil, and is able to withstand drought and other hardships, is often planted, especially in the Orient and in Africa, for the grateful shade its heavy foliage affords, as well as for its valuable fruit. This tree was early introduced by the Spaniards into Mexico and South America, and the experiments which have been made of late years with this tree in California seem to indicate that it may be depended on in that state, where its more general cultivation on ground too stony or too sterile to produce other crops can be recommended.

Our illustration is made from an Algerian photograph, for which we are indebted to Mr. Francis Skinner, of Boston.

Signs of Intelligence in a Madeira Vine.

TWO or three years ago I began, without any great seriousness, experiments on some Madeira vines, which presently began to prove more interesting than was anticipated. Before this my attention had been attracted to peculiar movements made by this plant in the course of its spiral ascent of a stick. If allowed to grow a few inches above this support the extremity of the plant will sway backward and forward a few hours and then will enter upon a regular revolving movement, always from right to left or contrary to the direction in which the hands of a watch move. One revolution consumes about three hours.

One of my plants began to grow on April 1st, and at the end of fourteen days was twelve inches tall and showing signs of uneasiness—now bending away from a vertical position and again standing nearly upright. On the 16th it was eighteen inches high, and being too top-heavy to stand erect, it began to fall away from the pot, which stood upon a table, toward the floor. This was done gradually and apparently with conscious care. It seemed to feel at times that it was letting itself down too fast, when it would stop with a jerk, like a nodding child, half asleep. When near the floor it began describing ellipses, about three inches in diameter, with its upturned extremity. On the 19th it was twenty-six inches in length, and would describe a crescent-shaped loop, seventeen inches in length by six inches in breadth in about two hours. On the 23d it was three feet and four inches long, revolved with less regu-

larity, and at times drooped as if weary or discouraged in trying to find something upon which it might entwine itself.

Thus far no opportunity had been given the plant to climb, since it was desirable to see what it would do to meet the absence of some support. On the 26th a new route of travel was undertaken at six o'clock in the morning, and at nine o'clock the extremity, which was near the floor, at the left side of the pot, had described a circle six inches in diameter. It then slowly swept around to the right side and made another irregular circle, and then returned to the left side of the pot; these movements occupied just twelve hours. The track of the tip of the vine was carefully traced with a pencil upon a sheet of paper laid beneath it, and the entire line of travel measured no less than six feet nine inches.

During the evening the plant became quiet, and probably remained so all night. At ten A. M. the next day, however, it began pointing its tip in various directions, and at noon assumed the form of a corkscrew, about four inches long, which posture it retained until night and then straightened out.

On May 1st the vine was lifted and tied to a vertical support—a large thread—where it remained entirely quiescent for two days. Then it began growing again as if it had recovered from what had been for six days a condition near the point of death.

Another vine was observed carefully during several days of cloudy weather. It uncoiled itself from the stick and reached away toward the light at an angle with the horizon of some forty-five degrees. It was carefully recoiled about its stick, but after it had grown some three inches more it unwound itself and stood away toward the window as before. Time after time during the continuance of the cloudy weather it was brought back to its support, but invariably left it. Then followed a fortnight of bright, sunny weather during which the vine showed no disposition to escape from its stick or stop its twining growth.

Attempts were made to induce another plant to twine in the direction opposite to its normal one, but no ingenuity could deceive the plant as to its proper course. All the experiments seemed to show how much like an animal was the plant in its sensitiveness, not only to changes of light and temperature, but to harsh treatment. Whenever restrained or forced, no matter how tenderly, out of its natural method of growth, all progress was retarded and the health of the vines disturbed in a marked degree. Plants seem to be creatures of feeling and the similarity of movement and of apparent purpose between them and the lower orders of animals are used to strengthen their theory by those who hold to the doctrine of the identity of life in the two kingdoms.

T. D. Ingersoll.

The Blue Gum Tree.

THE Australian Blue Gum, *Eucalyptus globulus*, has become one of the most prominent and characteristic features in southern California forestry. A tall, slender tree, attaining to an immense height, this native of Van Dieman's Land and Australia has taken firm root upon the Pacific coast.

Many a hillside and plain—a few years ago treeless, parched and brown—has been transformed into a mass of living green, furnishing the refreshment of shade and filling the air with a health-giving, grateful fragrance, through the slight encouragement given to this tree by man. From Eureka to Eusenada—a distance of nearly a thousand miles—this tree has steadily gained in favor. In its native land it grows to a height of three hundred and fifty feet, with a diameter of fifteen feet and more. Already many of the older trees on the coast range are from one hundred to one hundred and fifty feet in height.

A forest of Eucalyptus is something magnificent. Stately in proportions, the trees tower tall and straight above any of our indigenous species in the south, growing so close together as to form an almost impenetrable shade. Altogether it is a spectacle to gladden one's eyes in this "dry and thirsty land." Millions are already planted, and hundreds of thousands are annually planted because of the valuable qualities of the Eucalyptus as a forest-tree. Quick in its growth, it is an unfailing source of supply of fuel and valuable timber in a land where wood and lumber are scarce.

In San Diego County these trees are extensively grown for fuel, but thousands of them are also annually planted for their beauty, as shade or ornamental trees in parks and along avenues, while other thousands are planted as wind-breaks to young orchards, for which use they are well adapted.

The Eucalyptus is easily propagated from the seed, a pound of which may be obtained for five dollars. From this quantity of good seed over three thousand trees can be raised. The first seedlings sold in California, imported from Australia,

sold at auction for five dollars apiece. To-day they are worth a cent a plant.

The Eucalyptus thrives on the poorest soil, and once established firmly requires no further care or attention. It seems to do best on the sandy bottoms, but may also be made to do well on the higher mesa lands if once it is able to establish itself, when it will send its roots down a long way where it can get an unfailing water supply. That its culture on cheap lands is exceedingly profitable needs no further demonstration in California. A Eucalyptus-forest may be cut down once in every five (some say three) years to advantage, when new shoots will start from the stumps and a new forest arises from the ruins of the old, and without the first expense of either plowing, cultivating or irrigating, since the roots are already established, vigorous, healthy and uninjured by the fall of the parent trunk.

In the presence of the invigorating fragrance exhaled by this tree, fevers and malaria largely lose their terrors. In California, a dry, pure atmosphere like ours, the valuable quality of this tree, its anti-febrile properties, has naturally been largely lost sight of, as compared with other more important interests. The tree absorbs water with surprising facility, and it is this that is considered by many the basis of its prophylactic properties.

The Blue Gum or Fever-tree was introduced into Paris by the French government in 1860, and was subsequently planted in Africa, Spain, Italy and portions of France, where many large forests have been produced. In 1875 the City Council of Houston, Texas, decided to give the tree a trial in view of the yellow fever epidemics that had periodically filled the city with mourning. During 1875-76 the city was freer than usual from the disease, and in 1877-78, according to the Health Officers' report, was one of the healthiest cities in the Union. As to the subsequent experience of that city I have no data at hand.

The Eucalyptus shows remarkable celerity of growth, having attained a height of sixty feet in eleven years, and in India its growth has been yet more rapid. In Mexico it has succeeded remarkably well at elevations of from 2,500 to 7,000 feet. It has withstood a temperature of nineteen degrees F., but generally succumbs at seventeen degrees F. Frost will kill the young trees.

The timber is used for a great variety of purposes, in ship-building, and in all kinds of out-door work. It is about equal in quality to the best English Oak and to the American Ash, and if Californians will have the patience to grow the tree for timber rather than for fuel—as they now do almost exclusively—they might expect yet handsomer returns from its culture than now.

The tree is remarkably free of any disease and of insect pests; moths, mosquitoes, fleas and other insects are said to forsake a room where the leaf branches of the Eucalyptus are freely scattered about.

Notwithstanding there are over one hundred and fifty species of the Eucalyptus, *E. globulus* alone has met with widely extended popular favor in California. Several others like the Red Gum and the Iron-bark seem to thrive equally well with us and are gaining ground.

Thanks to this friendly genus it is only a question of a century or less before the now desert-like plains of southern California can be covered with a growth of gigantic trees.

San Diego, Cal.

C. R. Orcutt.

Nematodes and the Oat Crop.

THE Oat crop at the time of writing throughout New Jersey gives all the signs of failure. Many farmers have already plowed the fields again for some other crop, while many more are anxious to know what to do. In general appearance the Oat-plant is dwarfed, and nearly all the leaves, especially the lower ones, are brown and dead. As the wheat, rye and grass crops have been badly attacked this spring by the aphid or grain louse, many farmers have ascribed the wretched appearance of the oats to the same enemy, but I am assured by Professor Smith that the aphid cannot be held responsible for a great part of the destruction that is so widespread among the Oats of the state. Therefore it seemed advisable to make a microscopic examination of the diseased plants in order to discover whether the cause of this disaster was not some parasitic fungus. Specimens in root, stem and leaf, from several localities, have been examined, and nothing in the nature of a rust, smut, mildew, mould or blight was found. It may be true that a low form of organism belonging to the group of bacteria is the cause of the unhealthy growth.

Bacteria were found present, but no attempts were made to determine the bacterial origin of the disease.

But small bodies were found within the substance of the smaller roots and these at once suggested undeveloped worms of minute size called nematodes. As the search continued the mature worms were found in full activity.

Readers of GARDEN AND FOREST will remember an article on the Clematis disease, by Professor Comstock, which appeared in the number for January 29th of this year. In this article Professor Comstock showed that these minute worms, which are akin to the well known "vinegar eel," a minute creature often seen wriggling near the surface of vinegar, were the cause of this wide-spread disease of the Clematis. In a note of mine on Professor Comstock's paper, which appeared in the number for February 5th, it was stated that a part at least of the Violet-disease was due to a similar cause, and I mentioned the fact that Dr. Neal, of the Florida Experiment Station, and Professor Atkinson, of the Alabama Station, had each issued large illustrated bulletins which show the ravages of these thread-worms in the Peach and Orange-groves of the south. A species of these nematodes is said to cause the so-called tulip-root in Oats in England.

These worms are very destructive to some of our principal garden crops, and it is evident that a large field is opening in this country for the labors of the economic helminthologist. Unfortunately no cheap method has been discovered which can entirely defeat the attacks of the nematodes. One plan is to cultivate upon an infested area only such crops as are not attacked by these worms, so that they can be starved out, or if the rotation of crops is practiced unsusceptible plants may be used in some part of the rotation. As some weeds, the Pig-weed for example, furnish particularly favorable shelter for these microscopic enemies, they should be kept scrupulously subdued by clean culture.

Nematodes may be introduced into a field in composts and barnyard manure, and therefore it is wise, in case of a threatened invasion, to use unslaked lime in thin layers when constructing the compost or manure pile.

It will be noted that the two bulletins spoken of are from the far south. With us in the latitude of New York there is much less occasion for alarm in an ordinary season, for the cold of an average winter is too severe for these worms to withstand. The large numbers of nematodes that have been found upon various crops, such as Spinach and Violets, during the past winter, is probably due to weather unusually favorable to them. A winter warm enough to give us Peach-blossoms during almost every week from December to March was well suited to their rapid multiplication.

Corn is the only member of the Grass family mentioned in the printed lists of hosts for nematodes. The Oat, therefore, is an additional species in that family that is subject to these attacks.

New or Little Known Plants.

Trillium sessile, var. Californicum.

THE genus *Trillium* contains several attractive garden-plants. *Trillium grandiflorum*, the large, white-flowered species of the eastern and northern states, is the most beautiful of them, and when once established in a suitable position it is not excelled in beauty by any spring-flowering herb. The Painted Trillium, as *Trillium erythrocarpum* is called on account of the bright purple-rose colored markings which appear on the lower part of the petals, is hardly less beautiful, although the flowers are considerably smaller and much more modest than those of the better known species which we have referred to above.

Another plant of this genus, of first-rate value as a garden-plant, has been brought into cultivation in recent years. It is the Pacific coast form of a widely distributed eastern species, *Trillium sessile*, found from Pennsylvania and Wisconsin to Florida and Alabama. The western form of this plant, known as variety *Californicum*, is widely distributed through the northern part of California west of the Sierra Nevada and extends into Oregon. The habit of the plant and the character of the flower is represented in our figure on page 321, which is made from a specimen grown in the garden of Gillett & Horsford, of Southwick, Massachusetts, who have obligingly sent it to us for the purpose.

Trillium sessile, var. *Californicum*, is a stout plant

with broadly rhombic-ovate leaves varying from three to six inches in length, lanceolate, acute, erect sepals, and oblong or rhombic-obovate petals, which vary in length from one to four inches. These differ in color on different plants from purple to pure white and at first are nearly upright, becoming reflexed above the middle when the flower is fully expanded. The form with pure white petals is the handsomest and most desirable as a garden-plant.

The Pacific coast *Trillium*, like the other species of the genus, is most satisfactory when it is planted in deep, moist soil in the shade of deciduous trees; that is, where it can enjoy early in the season or during the blooming period full exposure to the light, and where later it can be protected by the leaves of the overhanging trees from the full blaze of the sun. *Trilliums* should be planted early in the autumn or not later than the first of October if good flowers are expected from them the following spring. They do not show, however, what they are really capable of until they have been allowed to grow undisturbed in the same spot during three or four years and have become well established. Then, if the soil in which they are planted suits them and the situation is a favorable one, they form broad masses of immense leaves and produce flowers of large size and surprising beauty.

Foreign Correspondence.

London Letter.—Pæonies.

AMONG the many beautiful border plants that have sprung into popularity in England in recent years, the Pæonies take foremost rank. Like the Daffodils, they were favorite garden plants in England over three hundred years ago. Gerard said of them in 1580, "All sorts of Pæonies do grow in our London gardens." The revival of a love for these and many other old-fashioned hardy plants may be traced to the development of out-door gardening and especially of the mixed border. Pæonies are essentially border-plants. They are hardy, easy to cultivate, almost any soil agreeing with them; they live to a good age and they flower freely. Their flowers are enormous, often elegant and fragrant, whilst their colors vary from deep purple-crimson to almost white. What could one desire more in a hardy border-plant? In England, Belgium and France nurserymen have done much during the last twenty years to improve the flowers in form and color and also to increase the number of good varieties. A collection of Pæonies is now a feature in all good gardens in June, whereas a few years ago they found admirers chiefly among the cottager. One of the principal raisers and growers of these plants in England, Mr. Kelway, of Langport, admits that he was first impressed with the beauties and capabilities of Pæonies on seeing them worn by the men and women assembled at an Irish wake some thirty years ago. Some of the best of the sorts he has bred from, he obtained from an old woman in his parish. The long lost *P. Whitmanniana*, a yellow flowered species, was rediscovered about eight years ago in an obscure Irish garden. Messrs. Barr & Son, George Paul, Ware and Kelway now possess an immense stock of Pæonies, an indication of their popularity in England. With a view to focusing the Pæony-knowledge and material, the Royal Horticultural Society has this week held a special exhibition of the plants, and papers on their culture, history and classification were read by Mr. George Paul and Mr. Lynch, of the Cambridge Botanic Gardens. The exhibits were marvelous in point of size, color and fragrance in the flowers, Messrs. Kelway staging a splendid array of blooms. Some of the new sorts received certificates. Whilst such beautiful double-flowered kinds as Princess Mary, Sainfoin, James Kelway and Lady L. Brumwell were greatly admired, the single flowered varieties received much attention. Some of them were remarkable for great substance of petal, far in advance of the older kinds, in which flimsiness of flower was a drawback. A deep blood-crimson kind named Stanley, a pink and white called Dorothy Tennant, and Julia Kelway, a blush white, were amongst the most notable of the single flowered sorts.

Tree Pæonies were not well represented, most of them being past flower here. The behavior of the Tree or Moutan Pæony in English gardens is not always satisfactory. In some situations the plants die a foot for every six inches they grow; in others they grow well for a time, and then go off suddenly, apparently attacked by some fungoid disease; whilst in some

gardens one may see immense bushes of them, eight feet in diameter, and bearing hundreds of huge blooms, each as large as a moderate-sized cabbage. Where they thrive these Tree Pæonies have few equals among early summer flowering hardy shrubs.

The Belgian and French nurserymen are the chief growers and raisers of Moutan Pæonies; Messrs. Makoy & Co., of Liege, and M. Dessart, Chenomceaux, Indre et Loire, having

suspected that the cause lay in this very fact. That there is not any close affinity between the tree and the herbaceous species is evident from their refusing to cross with each other, whilst there ought to be good physiological reasons against grafting a decidedly woody shrub on the roots of a plant of very succulent and herbaceous character. The right method, one would think, would be to use seedlings of *P. Moutan* as stocks. Herr Max Leichtlin, who has raised one

Fig. 44.—*Trillium sessile*, var. *Californicum*.—See page 320.

exceptionally rich collections. The species was introduced from China to Kew by Sir Joseph Banks in 1787. Many varieties have since been obtained from the same source. The great range of variation in size, form and color, and even in leaf characters, is remarkable in this species.

I believe it is the almost universal custom to graft *P. Moutan* on the roots of the herbaceous kinds, and in trying to account for the bad behavior of the Tree Pæony at Kew I have half

of the finest seedlings in Ceres, states that the seeds take about fifteen months to germinate, and the plants are from five to seven years old before they flower. Amongst the varieties grown at Kew the richest in color is that called *Gloria Belgarum*. The flowers are full double, a foot in diameter, and rich rosy red. These plants require a deep, rich, loamy, rather moist, soil, and a position shaded from very bright sunshine. In England they rush into growth so early

in the spring that a little protection must be given in frosty weather. When at rest frost does not injure them; indeed Fortune, who introduced many varieties into England, declared that a severe winter was conducive to their health.

The history of the herbaceous species, as represented in English gardens, was treated at some length by Mr. Paul. Almost all of the several hundred named kinds catalogued to-day are the progeny of *P. albiflora* and *P. officinalis*, a few only being from *P. peregrina*, and two or three from *P. tenuifolia*. Mr. Baker, in his monograph of the genus published in the *Gardeners' Chronicle* in 1884, admits only twenty-two species. They are distributed over Europe, temperate Asia, China and America. In the last-named country, *P. Brownii* is the only species that occurs wild. It extends from California to the Rocky Mountains. In 1884, and, so far as I know, even now, this species was not in cultivation in England. A hundred years ago *P. officinalis* and *P. grandiflora* were the only species recorded as being in cultivation in England. Mr. Paul says that the attention of the florist was not devoted to the herbaceous Pæony until about 1840, when Parker, Salter and Loddiges began to collect and cross them. In 1855 there were twenty-four double-flowered varieties, nine of which still survive in English collections. Lemoine commenced as early as 1824, whilst in 1840 the Prince Salm Dyck had a good collection of sorts in his then famous garden near Paris.

The cultivation of the herbaceous species was, Mr. Paul said, ridiculously easy. The richer the soil the better, of course, will be the results, for Pæonies are gross feeders. Mr. Wilkes, the Secretary of the Society, who showed a fine collection of flowers, stated that he emptied the cess-pools of his pig-sties upon his Pæony-clumps. They like plenty of moisture at all times. In shade, as well as in the open, they grow quite freely. Some of the growers of flowers for the London markets plant Pæonies under their orchard trees exactly as they do Gooseberries and Rhubarb; in this way they get a plentiful crop of flowers, which sell for about half a dollar a dozen. The most favorable time for transplanting is from November to February. Mr. Paul advised starting with small crowns in preference to large clumps, which rarely transplant satisfactorily. The third year after planting ought to see abundance of flower. The seeds take about a year to germinate, and the plants flower when four years old.

London.

Cultural Department.

Notes on Shrubs.

THE earliest species of Lilac in cultivation to bloom is *Syringa oblata*, while one of the latest is the large tree-like *S. Japonica*. The interval between these two extremes is from five to six weeks. As a sequence of flowering Lilacs is sometimes a desideratum the following data may give an approximate idea of the times of blossoming of the different species when growing under the same conditions. *Syringa oblata*, of which a figure from a photograph appeared in the first volume of GARDEN AND FOREST (p. 221), blossoms in this climate about the middle of May, varying with the rest of vegetation in being a little earlier or later according to season, situation and exposure. The bright lilac flowers of this species do not differ greatly from some of the forms of the common Lilac, and are no better, although the flowers of *S. oblata* have a peculiar character hard to describe, but which enables any one familiar with both to separate them easily. The thick, leathery, rounded, heart-shaped leaves are also so distinct as not to be easily mistaken. It has been claimed that these are not attacked by the mildew which often seriously injures some other kinds, but, in some localities at least, the foliage of this species is by no means exempt from the disease.

A week or more after *S. oblata* begins to blossom the first flowers appear on the earliest garden varieties of the common Lilac (*S. vulgaris*). One of the most precocious of these is the old double flowered, small paniced variety known in catalogues under the name of *Syringa vulgaris, flore pleno*. It is closely followed, however, by the numerous other forms originating from the same stock, or by the hybrids with other species, which are likely to be greatly multiplied and give rise to forms as early as *S. oblata*. Out of the hundreds of the so-called varieties of *S. vulgaris* now offered for sale, a selection of a dozen might be made which would practically include all of much value. A large number are being tested side by side at the Arboretum with a view to comparing the distinctive merits of their blossoms. For the amateur who has only space in his garden for one or two plants of this type there are few which can give more satisfaction than the old Charles the

Tenth as a dark red, and Marie Lagrange as a large flowered and large paniced pure white one. Both of these seem slightly later in flowering than the average of the forms and it is noticeable that the flowers maintain a fresh looking appearance for the longest time.

When the forms of *S. vulgaris* are grafted upon stock of the common Privet (*Ligustrum vulgare*) they make much more dwarf and compact plants and bloom sooner than when grafted on stock of their own species. The two Lilacs known as *Syringa Persica* and *S. Chinensis* blossom at the same time as *S. vulgaris*, and the flowers last as long as those of the best forms of the most common species. These plants are becoming even more common in some old gardens than *S. vulgaris*; and, on account of smaller size and more slender, graceful habit and the particularly large, thick clusters of flowers which they bear, they are too valuable to be omitted from the amateur's garden. There are forms of both with flowers varying in color from dark purplish red to white.

Syringa pubescens as it grows at the Arboretum has rather small panicles of pretty, pale lilac flowers, which appear with those of the preceding species. It is of rather straggling habit and does not present any marked peculiarities which would make it of special value to the horticulturist or florist. It is not until the last flowers of all these species and varieties have disappeared or are fading that the blossoms begin to expand upon the Asiatic *S. villosa*, and upon *S. Josikaea*, which is supposed by some botanists to be a variety of it. The inflorescence, however, is so strikingly different that it seems quite probable that they may yet be proved to be distinct species.

The first flowers of *S. villosa* generally appear at the end of the first week of June. The buds and outside of the corollas are of a rose or lilac color, but when expanded the open flower is very pale lilac or almost white. They are produced in broad, heavy clusters on rigidly upright branches, the whole plant having a coarse and stiff aspect. A figure of a flowering branch has been given in GARDEN AND FOREST, vol. i., p. 521. The flowers possess a good deal of odor, but it is less agreeable, though less intense, than that of the common Lilac.

Syringa Josikaea is not known in a wild state, and has all been propagated from a single plant found in a Hungarian garden. The slender, tubular, dark purplish flowers are produced in much smaller panicles than those of *S. villosa*; and as the plant does not appear to bloom so profusely as most of its congeners it is of less value for ornament. But on account of its lateness and the peculiar color of its blossoms it is not likely to be neglected or left out of any collection. These two species continue to maintain some fresh looking flowers for about a fortnight, and it is not until the last of them are fading that the blossoms appear on those species belonging to that section of the genus which have white flowers and very short tubular corollas. The two or three kinds in cultivation are all of quite recent introduction, and are as yet very little known outside of botanical gardens. The finest and most desirable of these is *S. Japonica*, which was described by Professor Sargent and figured from photographs in GARDEN AND FOREST, vol. ii., pages 293 and 295. The plants raised from seed appear variable in their time of flowering, a difference of a week being noticeable in specimens growing under very similar conditions in different gardens. Last season was an unusually early one, and the plant which was figured in GARDEN AND FOREST was in full flower about June 15th, but this year it did not reach the same stage of development until about June 24th. This plant is one of the earliest; others at this date (June 24th) hardly have the first flowers open. The small white flowers have a slightly creamy tinge of color, and in odor as well as general appearance they are more like gigantic panicles of the flowers of the common Privet than those of a Lilac. If it should be found possible to hybridize this splendid tree-like species with any of the Lilacs of our gardens some remarkable productions may be expected. The best plant at the Arboretum is now twenty feet high, with a clean trunk sixteen inches in circumference at four feet from the ground.

Syringa Amurensis has much of the appearance of *S. Japonica*, but so far seems to be inferior to it. A plant sold under the name of *S. Sibirica* seems to be the same as this. *S. Pekinensis* is flowering freely at the Arboretum this season. The flowers are smaller and a little purer white than those of *S. Japonica*, and the panicles are not quite so large. The whole aspect of the plant is strikingly different on account of its smaller leaves and much more straggling or spreading habit. The largest plant has now exceeded the stature noted by Abbé David when collecting about Pekin, who described this species as a shrub three metres (about ten feet) in height, and the white flowers exhaling an odor of honey.

The Carob-tree (*Ceratonia Siliqua*).—See page 318.

Notes on American Plants.

THE *Malvaceæ* or Mallow Family constitute an interesting class of plants, represented in North America by nearly one hundred and fifty species and varieties composed of herbs and shrubs. Many of these are already in cultivation, but there are still others that are destined to hold good positions among our garden flora. One of these, which we believe is not yet generally known, at least to American growers, is the Maple Leaved *Sphæralcea*—*Sphæralcea acerifolia*. It is found in the basin of the Columbia River and its tributaries, also in portions of Nevada and Utah, at from 6,000 to 8,000 feet in altitude. Its usual height is about four feet, yet in favorable situations it is sometimes six feet high. It is a herbaceous per-

ennial. The numerous stout stems terminate in clustered racemes, almost a foot in length, of pale purple flowers which are from half an inch to an inch and a half wide, and very pretty. Below these racemes are numerous large, cordate, five or more lobed leaves, shaped like those of the Maple, from which the plant takes its name. Its time of flowering is from June until September. It is hardy, easy of culture and should be grown in the sun.

Baptisia leucantha, one of the False Indigos and a member of the Pulse Family, grows from two to three feet high, bearing an erect, long, loose raceme of white flowers. It is a taller plant with less divergent branches than *B. leucophæa* mentioned in a previous paper. The foliage is not abundant. It is found in alluvial soil from Ohio to Wisconsin and southward. It needs a light soil and full sunshine.

Calochortus longibarbus, from Oregon and Washington, is a desirable species for this climate, as the plants show more health and vigor than most of this class here. It grows about a foot high, bearing from one to three, usually two, pale purple flowers an inch and a half wide. Across the base of each petal is a dark purple stripe which gives the flower additional beauty. Above this, on the inside, the petals have numerous long, white, hair-like beards almost an inch long. The leaf, which is usually single, is about eight inches long by half an inch wide. Our plants were protected during winter. It should be set in a light soil and exposed to sunlight in September or October.

Allium hamatochiton, from southern California, is a small species six or eight inches high, bearing an umbel of six to twelve small white flowers with greenish stripes and a reddish brown centre. It is a tender plant and should be wintered in sand in the cellar.

Tigridia buccifera, which was first figured and described in GARDEN AND FOREST (vol. ii., p. 412, Fig. 123), is quite abundant in portions of southern Texas. This we believe is the only species yet reported within our borders. It is one of the earliest if not the very first to flower. In a light, loamy soil it is not so large as in a clay loam, yet it seems to do fairly well in any ordinary situation and is much larger after being cultivated than when first taken from its natural home. Although its individual flowers are of very short life, they are borne in such long succession that a bed of them will be almost continually in bloom from the middle of June until early autumn.

One of the most common of the *Rubiaceæ* or Madder Family is the little Partridge Berry (*Mitchella repens*). This charming little evergreen at this season is covered with its pairs of small fragrant white flowers, a third of an inch wide. Later in autumn the pretty scarlet berries add much to its beauty, as they offer a pleasing contrast with the thick, dark green foliage. These remain on all winter, and both leaves and fruit are as attractive in spring as at any season. The foliage is often variegated with lighter lines. It does well in a fine loamy soil, where it soon forms dense mats of its prostrate, creeping stems.

Lilium Parryi, from southern California and Arizona, is a good native species, not difficult to grow in a moist, loamy soil, and bears one to several large, handsome yellow flowers, in shape not very unlike our common Meadow Lily. The flower is fragrant, durable and quite distinct in color from other yellow-flowered varieties. It is a healthy growing plant, hardy, if planted deep, and is sure to be a favorite when better known.

Southwick, Mass.

F. H. Horsford.

An Indispensable Greenhouse.

WHO loves a garden loves a greenhouse, too, but few love a greenhouse when they can enjoy the pleasures of a garden, with all its varying scenes from spring until winter, and then a greenhouse is a luxury to some, and to others a necessity. Of course greenhouses differ greatly among themselves. To persons of limited means the greenhouse is often a combination of a stove-house, Rose-house, Palm-house, Orchid-house, and a place for keeping bedding plants for summer flower-beds. Besides these there are succulents, subtropical plants, aquatics, which must be taken up and housed just as the Queen of Autumn holds levee, and space must be afforded for a few of the choice *Chrysanthemums* which cannot endure freezing temperature. Then *Primulas*, *Cinerarias*, *Calceolarias*, *Cyclamen* and a host of winter-flowering plants must be crowded in because flowers are looked for from a gardener "who has glass." I pity a man who has such a charge. It is impossible to keep or grow tropical plants in a cool house or to grow alpine plants in a stove-house. To be successful with most plants that are now to be found grown in glass structures there must be at least three houses of different temperatures, called in gardeners' language the stove-house, greenhouse and cool or cold house. The minimum temperature of the stove-house is sixty degrees; the greenhouse, fifty degrees; the cool house, forty degrees.

The cool house I consider a necessary adjunct to the greenhouse, and if only one can be built this is the indispensable structure. The style of the house is not the most important matter. A span roof undoubtedly will give the most light, which is an important point in the construction of a greenhouse, but the roof and sides are exposed to the full action of the weather. And this will tell in winter upon the coal bill. All things considered, I prefer a span roof house; the next best house would be a three-quarter span, such as those built principally for Rose-growing. This is a very useful and economical house. Its aspect should be due south if circum-

stances permit, making it a very light house in winter; and it should be protected on the north side by a wall. A lean-to is better than none at all, and can be attached to another building if suitably located; but such a house is not best adapted for plant growing. A very convenient house is a span-roof eleven feet wide, fifty feet long, four feet sides and seven feet six inches high in the centre. This will allow a three-foot six-inch bench or table on each side and a walk two feet six inches through the centre. Such a house requires only ventilators on either side of the ridge. Two-foot sash is preferable the whole length on each side, and a flow and return pipe three and a half inches in diameter will answer for heating. In such a house *Carnations* and *Mignonette* will flower all winter; *Stocks* and *Wallflowers* will furnish early bloom; *Cinerarias* and *Calceolarias* are quite at home; *Verbenas*, *Petunias* and many bedding plants can be safely housed; *Echeverias* and other succulents and dry roots will keep well under the benches, and it is just the place for *Chrysanthemums* from the time they leave the cutting bench until they are planted out.

Staten Island, N. Y.

W. Tricker.

Orchid Notes.

Phajus Humblotii.—When this beautiful species was first introduced and described by the collector as a rose-colored *Phajus* it caused a sensation among Orchid-growers. It is named in honor of its discoverer, M. Leon Humblot, who brought the plants to Europe some nine years ago. Very few arrived alive, and consequently large prices were realized for them. Several years elapsed before any attempts were made to reintroduce it, and the plant became almost extinct. Some twelve months ago an importation was received by F. Sander & Co., St. Albans, and it is now so widely distributed that few collections of Orchids are seen without it. It fortunately proves an easy plant to grow, it flowers abundantly and occupies little space. In habit it is both dwarf and compact, having robust rich green foliage, and produces a spike one and a half to two feet high, on which are borne twelve to eighteen bold and attractive blossoms, arranged in such a manner that each may be seen to advantage. They measure individually two and a half inches across; the sepals and petals are broad and suffused with a rich rose color; the lip is broad, the upper portion furnished on either side with reddish crimson; the crest is very prominent and of a fine bright yellow. While growth is being made, which is during the summer months, this plant requires a temperature of sixty-five to seventy degrees, with a position near the glass, but precautions should be taken that it does not receive direct sunlight. Ventilation is also highly beneficial, and when growth is fully completed water should be sparingly given, or growth will again commence before the flower-spike develops, which is immediately after the growth is made. This *Phajus* enjoys a compost of turfy loam, coarse sand and fine peat, with a portion of chopped sphagnum. There is a well-grown plant of this species in the collection of Mr. F. L. Ames, North Easton, Massachusetts, and when in bloom a short time since it was a strikingly beautiful object.

Phajus Henryii.—This is also a valuable acquisition, introduced by M. L. Humblot together with the plant above described. Few plants, however, were received, and they were afterward rarely seen in a thriving condition. A considerable number of plants were sent to Europe last year, together with the other *Phajus*, and they arrived in excellent condition, and the plant is now often seen growing luxuriantly. The blossoms of *P. Henryii* are paler in color than those of *P. Humblotii*, the lip especially being much lighter, the upper portion marked with brownish crimson and finely fringed. A plant is now in bloom in Mr. H. Arnold's collection at Eighty-fourth Street. The spike is erect and two feet in length, and carries seventeen blossoms, which greatly resemble those of *P. Humblotii* in shape. It is a charming species, and is admired by all who have seen it.

Summit, N. J.

A. Dimmock.

Papaver bracteatum roseum or Blush Queen is a variety which is said to have originated in an English private garden and has lately been distributed. It resembles the type in foliage and habit, but the flowers are quite unique, being pale blush pink, shading to deep red satin blotches at base of petal. In color effect it is something like the flowers of the Rose of Sharon (*Hibiscus Syriacus*), though brighter. It is a charming flower, though quite inconspicuous in comparison with the scarlet perennial Poppies, which are among the most vivid of flowers, though among a lot of seedlings there will usually be found some variation from bright orange-scarlet to blood red. The new variety seems to be the first decided break from

intense reds and leads one to hope for a pure white form—which would be a grand plant.

Scabiosa Caucasica is one of the choicest of hardy plants, and indispensable in any garden. The plants are dwarf, and the flowers, thrown well above the foliage on long stems, of a light lavender color and some three inches in diameter, are as pleasing as useful for cutting. Stock of this plant may be readily had from seed. The plants require a deeply worked soil, and if necessary to shift, it should be done with great care, as the roots extend deeply even in a young state. It seems reliably hardy in all stations in this latitude.

Silene inflata, the Bladder Campion of Britain, seems to have become naturalized in some of the eastern states, which is scarcely a matter of wonder, as some bits sent me have proved very prolific and vigorous and well able to hold their own among ordinary plants. This is an attractive plant with white flowers, globular capsules and graceful habit.

Elizabeth, N. J.

G.

A beautiful Rose in Mr. Waterer's nursery at Knaphill is the result of a cross between *Rosa rugosa* and a Hybrid Perpetual variety. It is not an exhibition flower, nor perhaps one that show-flower fanciers would care for; but the blooms are of an intense crimson color and as sweetly scented as the old Cabbage Rose, while the plant is free both in growth and bloom. This is the kind of Rose that many would admire, although it may show a little of its yellow centre, not only for its color, but sweet scent. A scentless Rose is without its greatest charm.

The Garden.

Color in the Borders.—Natural and easy combinations of color in the herbaceous borders are rare. They should not be difficult to obtain, although more forethought and time are required to produce them than in regular bedding arrangements. As the use of hardy plants for supplementing this expensive and unnatural style of gardening is in its infancy, we may, and shall, expect much improvement in the direction of proper arrangement of color. To show where experience leads, I can give a case where German Irises were planted indiscriminately among Ghent Azaleas. It was found advisable to remove all bronze and yellow-flowered varieties, as they marred rather than increased the effect intended by planting them. Another accidental case struck me as being to the point. A white and a pink variety of *Phlox decussata* had been planted near together, so that about a dozen stems of *Campanula glomerata* (blue-purple) from a neighboring clump fell closely amongst them; these together made a pleasing combination. For experiment I tried placing a few heads of *Lychnis Chalcidonica* (scarlet) with a view to effect, and also *Coreopsis lanceolata* (yellow). The combination, I thought, did not need either, and looked worse when both were added than with one only. Tall Delphiniums (blue) and *Thermopsis Caroliniana* (yellow) go very well together.

Correspondence.

The Study of Botany.

To the Editor of GARDEN AND FOREST:

Sir.—The recent articles in your journal with regard to the development of the powers of observation and the consequent increase of pleasure which spring from even a rudimentary knowledge of botany, have made me notice with especial interest certain passages in that delightful book of Richard Jefferies' called "The Open Air." Jefferies was one of the closest observers of Nature who has ever lived and written, yet throughout his life he prided himself on being a *dilettante*. I do not know that he would have used this word, but it is the one that fits the case. Nevertheless he was born to be something better. His dislike for the scientific student seems to have been as great, theoretically, as his scorn for the artist. Yet on every page he proves himself an artist born—one who noticed every faintest shade of color, effect of light and subtlety of form, and described them in words the full significance of which only an artist or a keen student of art can fully appreciate. And, on the other hand, he shows very often a yearning for that exact information which only scientific study could have supplied. In consequence of his neglect of both art and science, he was always a discontented lover of Nature. Finding no outlet for his passion, no purpose in his observing, he was continually questioning why beauty existed, what it implied, and how it was as beneficial as he felt it must be. In the essay called "Wild Flowers" we find singularly contradictory passages. For instance, he says, "The first conscious thought about wild flowers was to find out their names—the first conscious pleasure—and then I began to see many that I

had not previously noticed. Once you wish to identify them there is nothing escapes, down to the little white Chickweed of the path and the moss of the wall. . . . Plants everywhere, hiding behind every tree, under the leaves, in the shady places, beside the dry furrows of the field; they are only just behind something, hidden openly. The instant you look for them they multiply a hundredfold." Does not this suggest a mood which would have turned instinctively to botanical study and to books for easily won information? But no; Jefferies confesses how hard it is to discover common names from common people; he carries books with colored pictures around with him and mourns over their insufficiency and inaccuracy; he would like a botanist at hand to tell him what this thing is and that; but further than this in the path of inquiry he will not go. "If," he says, "some one tells you a plant, you know it at once and never forget it, but to learn it from a book is another matter; it does not at once take root in the mind, it has to be seen several times before you are satisfied—you waver in your convictions." Could anything be more singular as expressing the feelings of a cultivated man? It is as though he thought books were something apart from men—were not to be trusted, while the speaking voice might be. And does it not show that, after all, his interest in Nature was chiefly artistic—was concerned with beauty simply, not at all with facts? Otherwise he would have been impressed by that tracing of relationships between one plant and another which the printed page makes clear as spoken words very seldom can, and would have found his interest immeasurably increased by the ramifying facts thus made plain. It is, indeed, a curious study in psychology that Jefferies' book presents. A careless reader may be deluded by it into thinking that, since Jefferies could enjoy so well and describe so exquisitely, ignorance must be a blessing. But a more careful eye will trace on every page the record of a mutilation of pleasure, a limiting of intelligence, a missing of golden opportunities for which his ignorance of elementary scientific knowledge was alone responsible. He has given us a delightful series of books about Nature; had he studied a little botany they would have been twice as delightful to us, and he would have got thrice the delight he did from their making. He was always in some puzzle that he could not read, and the naive confession of the fact makes his essays often truly pathetic. Others, however, may profit by his example. The best of his words for them to remember are: "Once you wish to identify them there is nothing escapes;" and to these I venture to add on my own account, They can be perfectly identified only by a study of botany, and there is no study so easy (as far as the mere nature-lover needs to pursue it) or so pleasurable in itself. For few indeed must be the people in this time and land who share Jefferies' prejudice against books or his greater confidence in the spoken word of some chance companion.

Anthraxnose on the Maple.

To the Editor of GARDEN AND FOREST:

Sir.—Since the appearance of the note on the Anthracnose on the Oaks upon page 295 of GARDEN AND FOREST, many affected Oak-leaves have been sent to me from various parts of the country. Those from Salem County, Massachusetts, were unusually bad, and Mr. John Robinson, a keen student of dendrology, informs me that Buttonwoods never look well there, the leaves drying up in spring as if killed by frost. The purpose of this note, however, is to say that the same blight of the Sycamore and the Oak, *Gliosporium nervisequum*, attacks the Maple. A large White Oak tree about a mile from New Brunswick is badly infested with this leaf blight. Standing close to this tree is a Swamp or Red Maple (*Acer rubrum*), many of the leaves of which were brown and wrinkled in patches. These portions are found to be attacked by the same blight and present the peculiar characteristic of forming the spore patches along the leaf nerves as indicated in the specific name of the fungus. The leaves of the Maple upon branches interlocking with those of the deceased Oak were noticeably the most distorted. This makes three distinct groups of forest-trees susceptible to attack from the same Anthracnose.

Rutgers College.

Byron D. Halsted.

The Blight of the Sycamore.

To the Editor of GARDEN AND FOREST:

Sir.—In your issue of last week you ask for notes of the Sycamore disease, *Gliosporium nervisequum*. It has been known here for the past twenty years, and those who have been here that long say, "worse this year than ever." It is common at Bloomington, in the central part of the state; at

Rockford in the northern part; and at Hamilton on the Mississippi, across from the north-east corner of Iowa. Professor F. J. Burrill, in making a journey to St. Louis this spring, noted it all along the road nearly to East St. Louis. The trees in St. Louis were all in perfect health.

Professor Bailey, in the "Horticulturists' Rule-book," speaks of it as attacking the leaves in spring. That is hardly correct, since the damage has been completed or nearly completed the preceding year. The disease attacks the twigs of the current year's growth, nearly girdling them, but leaving them so that the buds can put out and make some growth before they are cut off entirely.

We have something else that is attracting our attention just now. A week ago brown spots were noticed on a hedge of Norway Spruce. On examination it proved to be the work of a spider, probably the same as the red spider of the greenhouse. Since then it has been making its presence known very rapidly. Whole trees here and there are beginning to take on a sickly look. It is hard to predict what may happen as the result of a hot, dry spell of weather such as we are likely to have at this season, but the Norway Spruce would certainly suffer seriously.

Agricultural Experiment Station, Champaign, Ill.

G. W. McCluer.

The Chrysanthemum Fly.

To the Editor of GARDEN AND FOREST:

Sir.—In the autumn of 1888 Mr. W. Rowe, of this city, selected the Chrysanthemum Mrs. F. Thompson as a seed-bearing plant, and placed it in a greenhouse with a number of varieties, mostly single, but exceedingly rich in color. The seed plant, which had only nine flowers, matured a considerable quantity of seed, which in due time was sown, and from which ninety plants were obtained. Out of this lot eighty-one flowered last fall, and at least one out of every four would be worthy of a place in any good collection.

Only one of these seedlings resembles the seed parent in a marked degree, but in form, color and size many of them partake of the characteristics of other varieties growing in the house, making it probable that some agent had carried to the seed-plant pollen of greater potency than its own.

This agent is a fly resembling somewhat the honey bee. It was most abundant in the fall of 1888, and is an industrious little creature, taking its daily rounds among the flowers in search of food. Being interested in it as a co-worker, and desirous to know more of its ways, a specimen was mailed to a friend, who sends the following note:

"The little yellow fly you send is probably *Meredon bardus*, Soy. Its larva is aquatic, and may live in the water tanks about greenhouses. It seems to be fond of the honey of flowers, and is frequently an inhabitant of greenhouses all winter. I give it credit of doing good work for me in crossing Chrysanthemums, consequently I rather encourage its visits.

"This fly is easily tamed, and three years ago I had two in my greenhouse that were so tame that they would come at my call and eat honey from my hand."

New Haven.

A. Veitch.

This matter of the Chrysanthemum Fly was brought to my attention last fall by Dr. John Hamilton, of Allegheny, Pennsylvania, who sent me a specimen for determination. He stated that certain growers of seed had bred this fly, and that the secret of their success was in the fact that by the aid of this insect they secured the most perfect cross-fertilization. The fly was a very familiar one to me, a supposed importation from Europe not more than twenty years ago, but one which has since spread all over the United States. In England it is well known as the "Drone fly," and its technical name is *Eristalis tenax*, Linn. In its early stages it is one of the "rat-tailed" larvæ, so commonly found in the filthiest excrement. The pupal stage is passed just underground, and the mature fly, strongly resembling in size and appearance a honey bee, is very fond of flowers, presenting the most complete change in habit and taste between the larval and imaginal stages. I have commonly found the fly in September on sunny fences everywhere, more especially near outhouses or barns. The secret of their presence in greenhouses is probably found in the presence of manure and compost heaps, which furnish the best breeding places for the larvæ, while the Chrysanthemums, by far the most gorgeous and prominent flowers at that time, attract the fly. There seems to be little doubt of the fact that the fly is an

efficient agent in fertilizing these flowers, but whether it is so exclusive as to merit the term "Chrysanthemum Fly" is quite another question. Dr. Hamilton assures me that seedsmen cultivate this fly and are very averse to give any information concerning it. The breeding is easily accomplished. The flies are everywhere, and a little encouragement in the shape of a filthy and rather shallow manure pit will provide for a full crop without further care. The *Merodon barda* (now *Mallota posticata*, Fabr.) bears a casual resemblance to *Eristalis tenax*, and the latter may have been mistaken for it. The larval habits are similar, and it is not without the bounds of possibility that there are two "Chrysanthemum Flies." *M. posticata*, however, is given a June period by Dr. Williston, who took it on blossoms of Dogwood and Blackberry. As to the distribution, *E. tenax* is recorded from Europe, Asia, Africa, North America and Japan.

John B. Smith.

A Hardy Plant Nursery.

To the Editor of GARDEN AND FOREST:

Sir.—A nursery of hardy plants is rarely more attractive than during the early summer, and any one interested in such plants will be repaid by a visit at this time to any of the establishments where they are largely grown, for a personal inspection will give one a better idea of their value than pages of description. When one is forming a permanent plantation or garden it is desirable to see the various plants well grown and in bloom when possible, as tastes differ materially, and in color especially one's own eyes are the best judges of what is satisfactory.

At the nursery of Mr. H. Meyers, Passaic, New Jersey, I found a few days ago many interesting plants. The Kæmpfer's Iris, partially in flower, made a display of unique bloom. To Mr. Thomas Hogg's first importation of this valuable flower have been added many more of varying merit, so that the collection of varieties here is quite complete. The large, beautiful, flat flowers, poised so gracefully over the reed-like foliage, have a remarkable variation over a somewhat limited range of colors—wine-reds, violet, purple and white. The flowering of *I. laevigata* practically closes the Iris season of the better known kinds. As seen in nursery rows the plants are not as attractive as when planted near water, but one notices sharp contrasts between the plants as to height and time of flowering.

Among other interesting plants in bloom were *Lilium Grayi* (GARDEN AND FOREST, vol. i., 19, Fig. 4), *L. Hansonii*, *L. Chalcedonicum*; Campanulas in great variety; Delphiniums in almost endless species and hybrids, the latter the gayest, though *D. formosum* will probably ever remain the favorite Larkspur. *Platycodon Mariesi*, the new dwarf species, is an interesting plant with large flowers. Its height of eight to twelve inches seems no great advantage, as the old *P. grandiflorum* and its white variety owe somewhat of their grace to their not too long stems. *Aquilegia Canadensis*, var. *flaviflora*, is a curious, though not showy, dwarf variety, with pale yellow flowers. *A. chrysantha* covered great breadths, but their brightness was somewhat dimmed by the yellow composites near. A mass of *Lychnis coronaria* (Mullein Pink), with silvery, woolly foliage and bright magenta flowers, contained also a few sports showing white flowers, with rose-colored pencilings. *L. chalcedonica* and the double variety, as also the white, and *L. Haageana* also represented this favorite flower in bloom. The latter variety, when it does well, is one of the most satisfactory of the family, its colors ranging from faint rose to brightest scarlet, being perfectly clear and distinct.

Two grand plants for sub-tropical gardens were noted; *Senecio Japonicus*, a large yellow composite, with deeply cut palmate leaves, and *Telekia spinosissima*, a wild-garden plant, with Inula-like yellow flowers, and broad, though somewhat coarse, foliage.

Other interesting flowers were *Salvia hians*, a fine blue, dwarfer than *S. patens*; *S. pratensis*; *Spiraea bullata*, the dwarf species with deep green foliage and dark rosy flowers, beautiful for edgings; *S. filipendula*, and its double variety; *Potentilla* in great variety; *Centaurea nigra variegata*, with excellent variegation and red thistle-like flowers; Perennial Peas, the white-flowered variety being one of the most useful and attractive of low vines; Geums, Alliums, Phloxes, Achilleas, those with silvery leaves the best; Coreopses; the graceful Bowman's-root (*Gillenia trifoliata*), and scores besides which might be named if a mere catalogue had general interest.

I must be allowed to mention, however, the curious Mosquito-plant (*Vincetoxicum acuminatum*) from Japan, which might be useful in some places. This is an Asclepidaceous plant with clusters of small white flowers which secrete a viscid juice. They are attractive to mosquitos, which are entrapped as they alight on them. At the foot of the hill just within the shade of the Beeches a colony of *Cypripedium spectabile*, finely in bloom, well repaid one for a journey.

New York.

G.

Periodical Literature.

The June issue of the *Kew Bulletin of Miscellaneous Information* is devoted to articles on compressed or tablet tea, which is manufactured at Hankow from tea-dust, and is now consumed in immense quantities in Russian Siberia. It appears that the volume of the brick tea trade is rapidly increasing and that the demand is becoming greater than the supply. To meet this, steam machinery has been introduced for the purpose of pressing the bricks, with the result that the steam-made article is more compact, better finished, and better able to withstand the long, rough journey it is obliged to make before reaching the consumers in Siberia. The following account of this interesting product is extracted from the report of the Commissioner of Customs at Hankow:

"The first operation is to sift the dust and reject all the sand and rubbish contained in it, usually amounting to about five per cent. It is then placed in a winnowing machine having three different sized sieves, with troughs corresponding, and passed into baskets. The residue, which is too coarse to pass any of the sieves, is taken out and trodden until it is reduced to the proper consistency, when it is placed in iron pans over a charcoal fire until it is sufficiently brittle, when it is again taken to be winnowed, and this operation is repeated until it has all been sifted to the requisite degree of fineness. Three sizes are produced, the coarser ones being employed to constitute the brick, while the finest dust is only used as a facing. The dust having been properly sifted, the next step is to prepare it for pressing, and this is done by exposing it to the action of steam for three minutes, and it is this steaming that robs brick tea of its scent and flavor, and for which a remedy is eagerly sought.

"The old-fashioned native apparatus consists of six iron boilers heated by charcoal, and having spaces above, which are fitted with rattan covers. When the dust is to be steamed it is spread out on a sheet of cotton cloth placed over the boiler and covered up; but with the improved European apparatus the dust is simply put into iron boxes and the steam then passed through them. After having been sufficiently steamed to make it adhesive, the dust is put into a strong wooden mould, on the movable cover of which the trade mark of the 'hong' or firm is engraved (so as to leave the corresponding impression on the brick), and firmly wedged down. It is then pressed and placed on one side for two or three hours to cool. Each brick should weigh one catty (one and a third pounds), and all those that do not come up to the proper standard of weight or are defective in any way are rejected and re-made. For this purpose they are taken to a rotatory mill, constructed of two heavy circular stones moved by a horizontal wooden bar, and working in a channel where the condemned bricks are thrown, and crushed as the wheels pass over them. Having again become dust, the operation already described is in all its details repeated. The hand press turns out sixty baskets a day with twenty-five per cent. of failure bricks, while the steam press produces eighty baskets a day, with only five per cent. of bad work, and the saving by the employment of the improved machinery amounts to one tael a basket, or, according to the above stated out-turn, eighty taels a day, or about £20 sterling. The bricks found to be correct in weight and free from defects are stored in the drying room for a week, when they are carefully wrapped separately in paper, and packed in Bamboo baskets containing sixty-four bricks each. Green brick tea is made in the same manner, but of leaf, not dust, and the bricks are larger, weighing two and a half pounds each, thirty-six going to a basket when packed for export."

There is an important article, too, on the timber-trees of the Straits Settlement, in which the botanical identifications of the trees producing the various timbers are given, with descriptions of these and their weight. One hundred and fifty different timbers are described in this list, the value of which is increased by the addition of an index of native and scientific names. The issue ends with a mass of correspondence carried on by the authorities of Kew with regard to west African cotton, with the view of calling attention to the subject of cotton-growing generally in this part of the world.

The June Exhibition of the Massachusetts Horticultural Society.

THE first of the principal summer exhibitions of the Massachusetts Horticultural Society is devoted primarily to Roses and Strawberries, although it serves to bring together always large collections of the other flowers, fruits and vegetables of the season. This exhibition was held in Boston last week and attracted the usual number of people which the queen of flowers always brings together in that horticultural centre. As far as the roses were concerned, the exhibition must be considered an average one only. Much better roses than those which were shown last week have been seen in Boston, and there have been many years when the flowers fell far below those of this season in quality and in numbers. As usual, the roses were well shown in the English fashion, in flat boxes, the tin cups holding the flowers being hidden by a covering of moss, which makes the best possible setting for the individual flowers. The roses, as a whole, were distinguished by a remarkable evenness of excellence which must have made judging a difficult matter, by good foliage and by flowers well colored but lacking something of substance, and certainly not of such enormous size as these shows have sometimes called out.

The Lyman plate for the best twenty-four named varieties of Hardy Perpetuals went to John B. Moore & Son, the second and third prizes in this class going to J. S. Fay of Woods Holl, a new exhibitor of roses, and to Warren Hustis & Son, of Belmont. President Spooner's special prize for the best twelve blooms of Ulrich Brunner went to Mrs. F. B. Hayes, of Lexington, for twelve very perfect flowers. In the class of twenty-eight distinct named varieties, Mr. John L. Gardner, of Brookline, carried off the highest honors. Very fine specimens of the American Beauty were staged by President Spooner, who also secured the first prize for the best eighteen varieties.

The following is a list of the varieties of Hybrid Perpetual Roses that appeared on the first-prize stands, the figure after some of the names referring to the frequency of their occurrence in different exhibits: Abel Carrière (3), Alfred Colomb (5), Antoine Mouton, Baroness Nathaniel de Rothschild, Baroness Rothschild (5), Beauty of Waltham, Boieldieu (3), Camille Bernardin (3), Catherine Soupert, Charles Darwin, Charles Lefebvre (4), Comte de Paris, Comte de Raimbaud, Comtesse de Chabillant, Countess of Oxford (4), Devienne Lamy, Dr. Sewell, Duchess of Bedford, Duchesse de Bragance, Duchesse de Vallombrosa, Duke of Edinburgh (3), Dupuy Jamain, Earl of Dufferin, Eclair, Edouard Morren, Emily Saxton, Etienne Levet (4), Eugenie Verdier (2), Fisher Holmes, General Appert, General Jacqueminot, Gloire Lyonnaise (2), Glory of Cheshunt, Heinrich Schultheis (2), Madame Alfred Rougemont, Mabel Morrison, Madame Boll, Madame Boutin, Madame Clemence Joigneaux, Madame Eugene Verdier, Madame Gabriel Luizet (7), Madame Julie Daran, Madame Marius Cote, Madame Montet, Madame Victor Verdier, Mlle. Emilie Verdier, Marchioness of Exeter, Maréchal Vaillant, Marguerite de St. Amand, Marie Baumann, Marie Finger, Marquise de Castellane (2), Maurice Bernardin (2), Merveille de Lyon (3), Miss Hassard, Mons. Boncenne (3), Mons. E. Y. Teas, Mrs. Turner, Mrs. John Laing (2), Oxonian, Paul Neyron, Penelope Mayo, Princess Louise (2), Prosper Langier, R. Dudley Baxter (new), Richard Wallace (2), Rosieriste Jacobs, Sir Garnet Wolseley, Thomas Mills (2), Ulrich Brunner (3), Victor Verdier (2), and White Baroness.

A collection of single Roses exhibited by the Arnold Arboretum attracted a good deal of attention, and the beauty of these flowers, judging by the amount of space given up to an account of them in the Boston papers, must have been a surprise to many people.

A few Orchids were shown by Mr. N. T. Kidder, of Milton, Mr. John L. Gardner, of Brookline, and Mr. E. W. Gilmore, of North Easton. Flowering Plants other than Orchids were not of first quality, and it is a commentary on the present state of horticulture in this country when a common scarlet Geranium makes its appearance on the exhibition stage in a class of greenhouse flowering plants.

Among Strawberries, Jewell, a light colored, well shaped berry which many people in the neighborhood of Boston have thought the best Strawberry of the season, won the highest honors, Mr. Samuel Barnett carrying off the Lyman plate with a basket of splendid fruit. Belmont was considered only second to Jewell. Mr. Benjamin F. Smith, of Cambridge, received the Society's silver medal for the best seedling, never having taken a prize, with Beverly. The exhibition of strawberries was, on the whole, very fair; and the size and beauty of the fruit has not been surpassed for many years. Strawberries, however, in

eastern Massachusetts, this season, lack something in flavor owing to the excessive moisture of the season and the absence of sun at the time the fruit was coloring. O. R. Robbins received the first prize, and Edward Hastings the second for two quarts of any variety of Cherries with handsome, well colored fruit of Black Tartarian.

The interest of the exhibition to lovers of wild plants was increased by large collections of these flowers, which are a specialty always at the Massachusetts shows.

Jacob Manning, of the Reading Nurseries, staged a large collection of hardy herbaceous plants, which we should be glad to describe more in detail, if room could be found.

Not the least attractive part of this exhibition was the display of Fox Gloves, grouped on the stage at the end of the upper hall, which produced a remarkable and striking effect.

Notes.

The profits accruing to the government from the sale of the fruit of the trees (chiefly Cherries) planted along the highways of Saxony amounted in the year 1889 to \$35,480.

In making hairpins for ladies' use an excellent aid to the gardener was unwittingly provided. Of many lengths and varying in thickness from a stout to an almost thread-like wire, there is nothing so handy for pegging down plants in the border.

Mr. Barkett, gardener to Lord Penzance, recently received a first-class certificate from the Royal Horticultural Society for a hybrid between the Sweet-Brier and Harrison's Yellow Rose. The foliage is larger than that of the Sweet-Brier, and somewhat fragrant; the flowers are single, two inches in diameter, pale salmon with a yellow centre.

Among the most interesting contributions made in recent years to the history of decorative art have been Mr. William H. Goodyear's speculations on the rôle played by the Egyptian Lotus in the ornamentation of Oriental, classic and more modern nations. Originally presented in lecture form, they have since been published in the *American Architect and Building News*; and now it is announced that they will be reproduced in atlas form, with illustrations of 2,500 objects and details, under the title "Grammar of the Lotus." An English gentleman, persuaded thereto by Miss Amelia B. Edwards, the well known Egyptologist, will supply the money for this costly enterprise.

In a late number of the *Illustrirte Gartenzeitung*, of Vienna, long quotations are made from the articles on *Taxodium distichum*, *Aster ptarmicoides* and *Aralia Cashmirica*, recently published in GARDEN AND FOREST, and to the Arnold Arboretum is given the credit for having introduced the last-named plant to European cultivators. Among the novelties recommended to its readers by the same issue of this journal are a number of plants of American origin; the Snowflake Rose, introduced by the Messrs. Strauss & Company, of Washington, *Ipomæa setosa*, *Euphorbia heterophylla*, introduced by Mr. L. W. Goodell, of Dwight, Massachusetts, and several Pines from our western states and from Mexico, which are not unknown in Europe but have been lost to cultivation in consequence of planting in regions of insufficient warmth.

A correspondent of the *Bulletin of the Torrey Botanical Club* says that half the 12,000 portraits of distinguished men of all times contained in the Wolff Collection of Engravings, recently presented to the Syracuse University, has now been catalogued, and that the list includes the names of 144 botanists. Modern celebrities are, of course, included, but the collection is especially rich in pre-Linnæan portraits. Nor did the collector confine himself to single examples, for six different portraits of Kaspar Bauhin are noted, seven of Erasmus Darwin, fifteen of Humboldt and no less than twenty-seven of Linnæus. Every style of engraving is represented, and the plates vary from duodecimo to folio size. If the University will permit historians and essayists to reproduce these portraits, the collection will be a most valuable possession to the country at large.

In a private letter recently received from Mr. C. G. Pringle, now engaged in exploring the flora of northern Mexico, he writes: "I find myself well located here for exploring the rich region between this city and Tampico. Twice a week at midnight a train leaves here for that place. About eight A. M. we enter the head of a wonderful cañon (3,100 feet elevation), which is full of profuse vegetation. After fifteen miles the train emerges from the cañon at eleven hundred feet elevation and enters the tropical forests of the lowlands. In my

last trip of two days in the upper end of the cañon I gathered five hundred specimens in forty species, half trees, and shrubs. There are a very few species here which I know. I have to come back here to dry my plants, as I can get food and shelter in only a few places below, and the vermin in woods and hovels are terrible pests. The rainy season has set in heavily. All the table-land has been dry and brown so far. My prospects are good."

French journals tell us that the estate of Elven, in Brittany, is offered for sale at the price of \$60,000. A better investment for this amount of money could hardly be imagined if the purchaser cared for picturesque surroundings and historic interest. Elven lies in a romantic country, close to Morbihan, the ancient stronghold of the Druids, near which stand the prehistoric dolmens of Carnac, while Auray, where King Arthur is fabled to have dwelt, is not far away. The estate itself comprises about 450 acres and a fairly well preserved castle with some other buildings. In this castle Henry Tudor, later King Henry VII. of England, was imprisoned when, after his mother's defeat at the battle of Tewkesbury, he was driven by a storm to the coast of Brittany and seized by its Duke. But the present generation will probably be more interested by the fact that it is the half-ruined tower of Elven which plays so prominent a part in Feuillet's "Romance of a Poor Young Man."

American Horticulture and more especially American Pomology has sustained a serious loss in the death of Patrick Barry. For fifty years he has been an active member of the firm which from small beginnings became famous the world over for enterprise, for accuracy and for business integrity. He has been untiring, too, with his pen, and as author and editor he always had some instructive message, and he always delivered it in a way that compelled attention. Many of the best horticultural societies of the country owed much to his organizing faculty and administrative force, so that it might be said that his influence has reached every orchard and garden of the country.

Patrick Barry was born near Belfast, Ireland, in 1816, and, reaching this country at the age of twenty years, he began his life-work as a clerk in the then celebrated nurseries of the Princes, at Flushing, Long Island. Four years later, with small capital, but with the knowledge of the business which he had acquired by a quick intelligence and persevering industry, he formed the partnership with Mr. George Ellwanger, in Rochester, in a business which since that time has constantly grown in power and influence and has become an honor to the nursery trade of the world.

While he was skilled in all branches of horticulture, he was specially devoted to pomology, and forty years ago his first popular work, entitled "The Fruit Garden," placed him in the front rank, with Downing and Thomas, as an authority in this field. Soon after he became editor of *The Horticulturist*, and conducted it with great spirit and intelligence until it was removed to Philadelphia. In 1860 he became Horticultural Editor of the *Genessee Farmer* and for six years was a constant contributor to that journal. For more than thirty years he was President of the Western New York Horticultural Society, a model organization of its kind, in which position he was always ready not only to give it his counsel, his time and his labor, but to make up any deficit in its treasury when its expenses were greater than its income. He has also been a member of the Board of Control of the State Agricultural Experiment Station, and here, as in other positions of trust, he gave his best thought to his labors for others.

Perhaps his most valuable work was the "Fruit Catalogue" of the American Pomological Society, which has been accepted as the standard authority on this subject, not only in this country, but throughout the world. He was Chairman of the General Fruit Committee of this body practically from its beginning, and the Fruit List, which is an exhaustive catalogue of the different varieties of fruits, with their peculiar qualities and degree of adaptation to different geographical locations, was his original conception and was practically carried out by him. But his restless activity was manifested in many other directions. He had accumulated a liberal fortune, and he was identified with the leading financial and philanthropic enterprises of the city of his adoption. Altogether he was a man of rare executive force, sterling judgment, and what was more important, of high character in all the relations of life. Honorable in business, liberal in charities, consistent in his religious profession, he won the hearty affection of those who knew him intimately and commanded the respect and confidence of the entire community.

The Scenery of New Hampshire.

THE mountain scenery of New Hampshire is one of the most valuable pecuniary possessions of her people. It will yield them increasing profits through all coming time if it is rightly cared for and protected from injury and destruction. The timber can all be utilized without destroying forest-conditions on the mountains, and the great manufacturing interests of the state require the preservation of the forests in the regions where the rivers have their sources. There is no important interest of the state which would not receive advantage from the permanent maintenance and intelligent management of her mountain forests. Is it not strange that our people everywhere are so slow to understand the truth that the forests would yield a great deal more timber if they were rightly handled than they do by the haphazard and murderous methods of lumbering hitherto in use? When we speak of forest-preservation multitudes of men still infer that if the forests are to be preserved, no timber can be cut or used. They seem to think that the only way to have timber for the boundless and increasing needs of the country is by destroying the forests, root and branch, and by the methods of lumbering still largely used the timber-producing capacity of extensive areas of land is every year permanently destroyed.

Timber in New Hampshire, and everywhere else, should be cut and used when it is ripe, when it is at its best. That is what it is for. But it should be cut in intelligent and civilized fashion, so that it will be reproduced again and again in a permanent succession of crops. There is no reason, or good sense, or profit in cutting off all the timber at once, large and small. All forest-lands should be carefully protected from fire, so that the forest-floor, and the soil out of which the trees grow, may not be destroyed. Every forest-fire is followed by the growth of inferior kinds of timber. A fire destroys in a few hours the elements of fertility in the soil which have been slowly accumulated by vegetable action through a thousand centuries of time.

The chief reason for preserving the forests of New Hampshire is the fact that they constitute the principal and essential charm of the remarkably beautiful and attractive mountain scenery of the state. If this scenery is

rightly cared for and preserved it will in a few years be more valuable than the agriculture of the state. While the mountain forest-lands are in private hands they are rapidly disfigured and rendered unsightly by thoughtless and reckless methods of lumbering. Why should not the state at once take steps for the acquisition of all the forest-lands which are essential to the attractiveness of the scenery and to the maintenance of the flow of the rivers of the state? The people of New Hampshire ought to have faith in the future of their state. If they will protect their forests, let the trees grow, and improve their roads they will in a few years have summer visitors and summer residents enough to utilize all the beauty of their wonderful mountain landscapes. Travelers and towns-people from all parts of the country, and of the world, will gladly pay liberal tribute for the privilege of a summer sojourn among the hills. The revenues of the inhabitants will be largely increased, and their lives rendered easier, broader and more interesting. The use of the natural scenery of New Hampshire is to be the great future interest and industry of her people. It will admit of great development and expansion. We do not need to fret about the abandoned farms. Let them grow up to pine timber again. They will then be more valuable than they are now. Many of them ought never to have been cultivated, and if forest-conditions had been maintained on them they would now sell for much more money than they will bring in their present condition. But the forest will reassert its ancient dominion. One of the best things about the country up there is the way the Pine-trees come in wherever the plow stops for a little while. No need to talk about planting trees in that region.

We presume the intelligent and thoughtful men of the state would be glad to see the mountain forest-lands made a public possession, so that lumbering could be carried on in an orderly way, so that forest-conditions might be permanently maintained, the beautiful scenery preserved, and an ever-increasing multitude of summer visitors attracted to the great mountain houses and to the hill farms. But the population of the mountain regions of the state is scarce and scattered. The owners of the forest-lands live in the cities or out of the state. They do not often see each other, and it is very difficult to bring about any conference, general consultation or common action among them. This is indeed the greatest obstacle in the way of needed action for the preservation of the forest and the scenery. The state should have an officer to attend to these interests and to bring about the general co-operation of the people, in view of the increasing demand for timber, and of the approaching expansion of the summer business, not only at the mountain hotels, but on the hill farms.

THE article by the Earl of Meath, an abstract of which is given on page 338 of this issue, is interesting to Americans because it shows how our city parks appear to the eyes of an Englishman who has had much experience in the management of public pleasure-grounds. Some of our American ways are specially commended by the writer, and one of these is the general practice of entrusting the administration of city parks to small boards of commissioners, with ample and almost unrestricted powers. There can be no doubt but that definiteness of policy, with promptness and vigor of action, is made possible by such a government, and perhaps it never occurred to our friendly critic, who has a civilized respect for professional counsel, that a commissioner would undertake the proper work of a landscape-gardener any more than the director of a railroad would attempt to design a drawbridge or build a locomotive. But just here lies the danger of such an administration. If it is urged that only a densely ignorant man would esteem an appointment by a mayor an adequate preparation for the work of designing a park, the answer is that men of fair business ability who have been made park commissioners have on more than one occasion proved that they considered their own crude notions superior to the carefully studied opinions of recognized experts.

But a few days ago two of the Park Commissioners of this city voted to spend at least \$300,000 for the obliteration of one of the most beautiful meadows of Central Park, and that, too, after their attention had been directed to the fact that the great defect of the park is its scanty area of open greensward, and that the greater portion of the turf had been won from the rocks at enormous expense by blasting away the ledges and carting in loam to replace them. They did seek counsel of Mr. Vaux and of Mr. Olmsted, who together designed and constructed the park, and both of these artists not only strenuously opposed the scheme, but gave convincing reasons for their opposition to it; and yet the Commissioners acted in direct violation of the advice they solicited. The meadow is to be sacrificed, if the scheme is not frustrated, in the interest of a sorry collection of animals, although the spot has been shown to be in every way unsuited to their health. It has no water, cannot be properly drained, has not a sunny aspect, is shut off from cool breezes in summer and has no protection against the cold winds of winter. To make ready for the cages 25,000 square feet of rock will need to be blasted out and many of the stateliest trees in the park must be destroyed. The President of the Board admits that he only contemplates a temporary use of the meadow for his colony of beasts, and for this he is willing to spend half a million dollars and leave unsightly wounds upon the face of the landscape, which, with the best of care, cannot be healed in a generation.

No one would think of consulting either of these men about the planning or planting of a country door-yard with a reasonable hope of receiving any advice worth listening to, and yet they have no hesitation about deciding upon critical questions of park design and construction. The fact that they have never had any training or experience in such matters does not restrain them from acting with entire confidence in the soundness of their judgment. They plainly have a supreme contempt for any view which conflicts with their own, and they reject without consideration the advice of the very men who are recognized by all the world as the most competent to give an opinion.

Small park boards, with ample powers, may be preferable to large ones, all things considered. But certainly parks are never free from danger when a majority of the board controlling them consists of two or three men who have no respect for expert opinion, who have no clear ideas of the intricate nature of the problems which must be solved when a park is successfully designed, who do not even understand that any question as to plan or construction can possibly present itself which the average American citizen is not competent to answer off-hand. As a matter of fact, the most serious attacks upon the integrity of our city parks have been organized by the men who were chosen to protect them.

THE Philadelphia *Inquirer* of June 23d mentions the sale of 87,000 acres of forest-lands in Pennsylvania to men from outside of the state, and says that the timber is likely to be cut off in a more sensible manner than if these lands were, as hitherto, divided into many small holdings. It is probable that timber lands in the eastern states would be a more profitable investment for capital than some of the enterprises which have been popular during the last few years, but this depends very much upon the feeling and usages of the communities in which the lands are situated. Pennsylvania has, or had very recently, a law for some of the mountain counties of the state which always brings disaster to forests, a statute permitting cattle to run at large. This leads to the practice of starting forest-fires for the benefit of the pasturage, which results in the destruction of much valuable timber, and in the rapid elimination of the fertility of the soil of large areas. Great injury has already been done in the mountain region of Pennsylvania, and it will be interesting to observe the effect of the improved methods of forest-management which the *Inquirer* thinks will be adopted by the new purchasers.

A Japanese Pot Plant.

READERS of garden literature have in late years become familiar with the descriptions and illustrations of the dwarfed conifers of which the Japanese are so fond. Less is known of their dwarfed deciduous trees, a portrait of one of which appears in our illustration on page 335. It is a weeping double-flowered Cherry, in which the Japanese specially delight, and which they grow in great numbers for the decoration of their gardens, often grafting them to assume curious and abnormal forms, and cherishing them year after year among the most precious of their household belongings.

Our illustration was made from one of a large series of photographs of these plants taken in Japan by Dr. William Sturgis Bigelow of Boston, who has favored us with a set of them.

Water in Landscape-Gardening.

WATER is an essential element in the beauty of a landscape, whether it is presented as sea, lake, river or running brook, and no landscape-gardening can be perfect without its addition in some form. While all admit the grandeur of the ocean and the beauties of the lake, with its ever-changing surface, in the selection of a country home, that spot should have the preference which combines with other advantages a running stream in the form of river or brook. It should be a rapid stream, boiling over a pebbly bed and noisy enough to lull one into healthful slumber as he lies down to rest at night. Just such a stream is the upper Saco, among the White Mountains of New Hampshire, where it rushes over a rocky bottom, through the farm of the elder Crawford, and fills that charming valley with its murmurs. Such a stream is the Tweed at Abbotsford, among the Scottish hills, whose rippling, so dear to Walter Scott, was the only sound, as Lockhart tells us, that on that summer's day broke the stillness of the death scene when the great man passed away.

He is fortunate who, with other elements of beauty about him, can combine upon his own grounds these of which we have spoken, or in the absence of these, even the cool, sparkling spring bubbling up in some Fern-embroidered dell.

But if one cannot possess either the rushing stream or the trickling rivulet, he may in a degree supply their lack or even supplement them by the construction of artificial lakes and fountains. These may be costly enough; but water can be introduced into any garden in a modest way so as to be within the reach of moderate means. Of course the water supply is the first item to consider in the construction of a fountain. If this is provided by a city or town the character and volume of the fountain need only be regulated by the owner's purse. If water comes from a neighboring brook by a hydraulic ram or by means of a windmill, the fountain of course must be regulated by the size of the reservoir. Where this supply is limited, a weeping fountain, which consists of an upper basin into which the water is brought with just sufficient volume to overflow on every side into a larger basin below, is perhaps to be preferred. By carrying the pipe to a level with the outer edge of the upper basin the water may be thrown a little above the surface in a jet, or it may be allowed to boil up in the basin. In material and design such a fountain may be infinitely varied. An inexpensive arrangement was carried out in this way. The vase, or upper basin, was formed of an irregular shaped block of freestone, nearly circular and some three feet in diameter. This was supported upon three blocks of the same kinds of stone placed with apparent carelessness one upon the other, the lowest resting in the centre of a lower basin, which was circular and some five feet in diameter. The blocks were drilled for the passage of the conduit pipe and the whole was rough-hammered. The spray of the water which dripped from the upper basin quite sufficed to moisten the Ferns and aquatic plants set about its base and the color of the freestone was quite in harmony with its surroundings.

A rustic, spring-like fountain when placed amid suitable surroundings and away from buildings, can hardly fail to please. The supply pipe may be concealed behind well arranged rock-work and water can flow or trickle down from stone to stone into a basin below. If these stones are selected from the borders of a stream and are well covered with moss, or from an old stone wall and are encrusted with lichens, the general effect will be greatly heightened. If the interstices are filled with soil an excellent place is provided for the growth of Ferns and of climbing and drooping plants.

A wall fountain is suitable to be placed in connection with

buildings, especially with those where the basements at least are made of stone. A shallow archway of rough brick or of unhammered stone is needed, the conduit pipe being brought to the mouth of a griffin's or of a lion's head placed at the upper part of the arch with the water pouring into a basin below. Where the water supply is still more limited, an effect which is quite pleasing may be produced by allowing the water to drip from a shell in which the supply pipe is introduced down to a larger one and again into a larger one still. In any case English Ivy or *Ampelopsis* may be trained about the arch.

There is no limit to the designs and decorations which ingenuity and taste may devise for artificial fountains. One cardinal rule, however, should in no case be violated. That is, the water should not be made subordinate to the architectural display—and this rule should be observed especially when the water supply is limited. The rule is constantly violated, however, in public grounds and on private estates.

Chestnut Hill, Mass.

Daniel D. Slade.

The Cedars in Europe.

THERE is no difference in the hardness of the Cedar of Mount Lebanon and of that of the Atlas, when these trees are planted in Europe. The two grow well all over southern Europe, although an exception must be made to the hot and exceedingly dry region on the shores of the Mediterranean, where they cannot exist; for it must not be forgotten that the Cedar is a plant of high mountains, which demands a certain amount of humidity, and which cannot bear an exceedingly dry soil. The northern limit of the region where Cedars can be grown in Europe ascends from the east to the west, a well known phenomenon noticed also in the case of many other plants like the Beech and the Holly which do not support an excessively cold climate; and shown in the fact that the mild, rainy winters which distinguish the climate of the Atlantic coast of Europe are singularly favorable for southern trees. The Cedars follow this line and succeed admirably in the parks of Great Britain. Probably nowhere, not even in Syria nor on the Atlas, can such splendid groups of Cedars, relatively young, although already of imposing size, be found as are seen in the gardens surrounding English villas and castles. There is a famous old plant in the garden of the Museum at Paris, now beginning to fail, which is popularly but incorrectly supposed to have been brought home by Tournefort from the Orient. The sandy shores of the lakes which follow the southern slopes of the Alps afford conditions where the Cedars grow perhaps as well as they do in England, although in the north of Switzerland and in the Vosges the Cedar is occasionally subjected to too severe cold, and so perishes perhaps once every ten or twenty years. In Germany this danger is increased and there are in that country only a few sheltered localities where the Cedar can live.

The Cedar of the Atlas is less commonly cultivated than that of the Lebanon. It must be acknowledged, too, that the former, with its shorter leaves and more compact ramifications, is less agreeable in aspect and more severe in outline than the classic tree of Syria. The largest specimen of the Atlas Cedar which I know is in the celebrated garden of M. Thuret, belonging now to the French Government, and directed by the Nestor of French botanists, the venerable and distinguished Naudin. This tree is seventy-five or eighty feet high or more, and very vigorous. The leaves are short and it is easily distinguished at a glance from the Asiatic variety.

The Deodar has in Europe a more restricted range than the other Cedars. It grows well only where such evergreens as the Laurel, the Arbutus and the Laurel Cherry thrive—that is to say, along the Atlantic coast as far north as southern England and in the region of the lakes south of the Alps. Here it is a tree of great beauty, far more graceful than its congeners of Syria and of the Atlas; it is distinguished by its longer and richer leaves, and by its slender, graceful branches, pendent like those of the Weeping Willow, and by its enormous size. It is, however, on the shores of the Lake of Geneva at the extreme limit of the region where it can be grown successfully as a tree, although north of the Alps it is possible to have graceful young plants during several years. Sooner or later, however, generally once every five to six years, these plants either suffer badly or are killed outright by a severe winter, just as the Araucaria of Chili and the Fir of the Himalayas are killed occasionally.

In order to realize how beautiful trees can be, one should see the Deodar in some of the gardens on the shores of Lake Maggiore, growing with the most beautiful evergreen in the world, the *Magnolia fœtida*, which flourishes so well there, and which is covered year after year with its immense

flowers, which appear to float on the shining, dark green mass of foliage like Water Lilies on the dark mirror of some lake hidden in the forest. This union of the most beautiful conifer of the east with the most beautiful evergreen of the New World is, without doubt, the most delightful effect of vegetation which that fortunate region of the Italian lakes can offer. The Riviera of Geneva, although hotter, is too dry for the satisfactory development of such delicate trees; but would it not be possible to bring them together in Carolina, or Florida, or Louisiana, in the country of the Magnolia?

Bâle, Switzerland.

H. Christ.

Notes on North American Trees.—XVIII.

Description of the Wood of Certain Species.

A CRITICAL examination of the wood produced by the trees of the United States formed part of the investigation of the forest-wealth of the country made in connection with the taking of the tenth census. Mr. S. P. Sharples, a special agent of the department, had immediate charge of this branch of the investigation, the results of which appeared in volume ix. of the Final Reports of the Tenth Census, pages 247 to 481.

One object of this investigation was to determine the fuel value of the woods of our trees. It was found impossible, however, to obtain at the time it was made the wood of a few rare trees; and a number of others have been discovered since it was completed. The wood of several of these I have now received from the American Museum of Natural History, in New York, for examination. This material has enabled me, through the liberality of Mr. Morris K. Jesup, the President of the Board of Trustees of the Museum, whose interest in the forest-products of this country is testified to by the superb collection of American woods he has caused to be placed in the Museum, to continue the experiments necessary to determine the fuel value of the woods which were not included in the census report. The calculations have been made by Mr. Sharples, who has used the methods adopted in the Census investigation.

The wood specimens used for specific-gravity determinations were 100 millimeters long and thirty-five millimeters square, and were dried at a temperature of 100 degrees centigrade until they ceased to lose weight. The specific gravity was then obtained by measurement and calculation from the weight of the blocks. The determinations of ash were made by burning small dried blocks in a muffle furnace at a low temperature. The relative fuel values were obtained by taking the percentage of ash from the specific gravity and are based on the hypothesis that the value of the combustible material of all woods is the same.

The woods will be taken up in the botanical sequence of the trees which produce them, the descriptions being made uniform with those of the Census report.

The wood of a few North American trees has not yet been examined. The first of these is *Gordonia Allamaha*, an exceedingly local species of Georgia, and last seen growing in its only known station a hundred years ago. Recent attempts to rediscover it have proved futile and it is now only known in cultivation. Other species whose woods we have not been able to examine yet are *Rhamnus crocea*, var. *insularis*, *Pithecolobium brevifolium*, *Aralia spinosa*, *Fraxinus cuspidata*, *Quercus Leana*, *Quercus Macdonaldii*, *Quercus Morehus*, *Juniperus flaccida*, *Pinus latifolia*, *Pseudophœnix Sargentii*, and an apparently arborescent Palm of the Florida Everglades, of which I have only seen a leaf and a slender stem. These species either are not represented in the collection, or the specimens do not afford suitable material for such investigations. The wood of *Pseudophœnix* decays so rapidly after it is cut that it was impossible to determine its specific gravity. *Juniperus flaccida* is a Mexican species only seen within the limits of the United States in a single, very inaccessible region of western Texas. *Pinus latifolia*, the latest addition to the trees of the United States, is only known in a single locality of the Santa Rita mountains of Arizona, and has only been seen by its discoverer, Dr. H. Mayr. The wood is not known. *Quercus Leana*, at one time believed

to be a natural hybrid, but now, perhaps, best considered a species, as it is found occasionally in widely separated regions, is not yet in the collection. The other Oaks are still doubtful California species, of which comparatively little is yet known.

The following species are contained in Mr. Sharples' new investigation:

Helietta parvifolia. Wood hard, very heavy, close-grained; layers of annual growth marked by several rows of minute open ducts; medullary rays numerous, very obscure; color light orange-brown, the sap-wood rather lighter colored; specific gravity, 0.8785; ash, 1.83, 1.90, average 1.87; weight per cubic foot, 54.75 pounds; fuel value, 0.8621. Collected by C. G. Pringle in the valley of the lower Rio Grande.

Koeberlinia spinosa. Wood very hard, heavy, close-grained; layers of annual growth faintly marked with numerous minute open ducts; medullary rays thin and obscure; color dark brown more or less streaked with orange, turning nearly black with exposure, the sap-wood clear, pale yellow or nearly white; specific gravity, 1.1062, 1.1344, average 1.1201; ash, 0.16, 0.25, average 0.21; weight per cubic foot, 69.80 pounds; fuel value, 1.1177. Collected by C. G. Pringle in the valley of the lower Rio Grande.

Ilex monticola. Wood hard, heavy, close-grained; layers of annual growth hardly distinguishable; medullary rays numerous, thin; color creamy white; specific gravity, 0.6746, 0.6379, average 0.6562; ash, 0.41, 0.56, average 0.49; weight per cubic foot, 40.90 pounds; fuel value, 0.6631. Collected by F. H. Boynton, near Highlands, North Carolina.

Ceanothus velutinus, var. *arboreus*. Wood heavy, hard, close-grained; layers of annual growth clearly marked with broad bands of minute open ducts with irregular groups of ducts between them; medullary rays thin, very obscure; color light reddish brown, the sap-wood nearly white; specific gravity, 0.7781; ash, 2.05; weight per cubic foot, 48.49 pounds; fuel value, 0.7622. Collected by T. S. Brandegee on Santa Cruz Island, California.

Rhus integrifolia. Wood heavy, hard, containing numerous scattered open ducts; layers of annual growth distinctly marked with broad, open ducts; medullary rays thin, numerous, very conspicuous; color bright clear red; specific gravity, 0.7500, 0.8160, average 0.7830; ash, 0.20; weight per cubic foot, 48.80 pounds; fuel value, 0.7815. Collected by C. R. Orcutt in Lower California.

Cercidium floridum. Wood light, soft, close-grained, satiny, susceptible of a good polish; layers of annual growth marked by one to three rows of open ducts; medullary rays numerous, thin, conspicuous; color pale yellow faintly tinged with green, the sap-wood rather lighter colored; specific gravity, 0.5217, 0.5149, average 0.5483; ash, 2.66, 2.21, average 2.44; weight per cubic foot, 34.17 pounds; fuel value, 0.5348. Collected by C. G. Pringle in the valley of the lower Rio Grande.

C. S. Sargent.

New or Little Known Plants.

Ptelea aptera.

THIS plant, a native of Lower California, is interesting from the structure of the fruit, which differs from that of the other species of this small North American genus. In other *Pteleas* the indehiscent fruit is surrounded by a broad reticulate-veined wing, while in *Ptelea aptera* it is turgid, nut-like and glandular, and quite wingless, or with a narrow rudimentary wing only.

Ptelea aptera is a densely branched, pungently aromatic shrub, with slender stems growing to a height of five to fifteen feet and forming dense clusters. It is quite similar in habit and in general appearance to the common *Ptelea angustifolia* of the southern and south-western states, and, except for the fruit, might almost be mistaken for that species.

The fruit is broadly ovate, lenticular, and slightly keeled; it is wingless or nearly so, a quarter to half an inch long, and a quarter of an inch broad; slightly emarginate at the

base, tipped with the remnants of the persistent stigmas, and conspicuously glandular. It is two or rarely three-celled. The seeds are oblong and corrugated, with a shining black testa.

Ptelea aptera was discovered in January, 1883, on dry gravelly slopes near the shore at Punta Banda, at the southern end of Todos-Santos Bay, by a party of botanists under the leadership of the late Dr. C. C. Parry. Flowers and remnants of the fruit of the preceding year were found at this time. Dr. Parry read an excellent account of the plant with diagnostic characters before the Davenport Academy of Science in December, 1883. This was afterward published in the proceedings of the Society (iv., 39), the ripe fruit, in the meantime, having been collected by Mr. C. R. Orcutt, of San Diego.

Our illustration (see page 333) is from specimens collected by Messrs. Parry and Orcutt and preserved in the Gray Herbarium of Harvard University. C. S. S.

Plant Notes.

Some Recent Portraits.

THE most interesting plant, from a garden point of view, figured in the June number of the *Botanical Magazine*, is the Japanese *Rosa multiflora* (t. 7119), one of the most beautiful of all hardy flowering shrubs. It was first made known more than a century ago, but only found its way into gardens very recently, a fact which adds to its interest, especially as some of its double forms have been for years familiar garden ornaments. A figure of this Rose, from a drawing made by Mr. Faxon, has already been prepared for GARDEN AND FOREST and will be published during the present summer with a fuller account of it than it is now desirable to give.

The same number of the *Botanical Magazine* contains a figure of a beautiful warm-house climbing plant—*Allamanda violacea* (t. 7122). This species, which is a native of Brazil, differs principally from the other *Allamandas* known in gardens in the color of the flowers, which are rich rosy purple. *Allamanda violacea* was cultivated in England as long as thirty years ago. It was soon lost, however. Fortunately, the plant was kept alive in the Botanic Garden of Natal, whence it has been sent to England again, where it flowered at Kew last autumn. It is a very desirable and beautiful plant, demanding the treatment under which the other species flourish, and well worth growing with them on account of the color of the flowers.

There are figures also of a *Carludovica* (t. 7118) of unknown origin, for which the editor proposes the name of *C. Caput Medusæ*; of *Hemiorchis Burmanica* (t. 7120), representing a genus of *Scitamineæ*, of which only a single species is now known and which possesses little value as a garden plant; and of *Tillandsia amethystina* (t. 7121), from southern Brazil.

Monsieur Carrière describes in the *Revue Horticole* of June 1st a curious semi-prostrate form of the Norway Spruce under the title of *Picea excelsa reflexa* (f. 73). This was one of the interesting plants shown by Croux & Co. at the Paris Exposition of last year. It forms a bush only a few feet high, with irregularly pendulous branches, a habit which particularly fits it to spread over rocks or to plant in rocky situations.

The *Gardeners' Chronicle* of the 31st of May contains the reproduction of a view taken in a Garden of the Scilly Islands, in which is growing a splendid mass of *Puya Chilensis* (f. 115), one of the most beautiful of all Bromeliads. The leaves form a great Agave-like cluster, from the centre of which rises a tall flower-stalk, terminated by a dense head of bronze-blue flowers of exceeding beauty. This would certainly be an admirable plant for California, although it is hardly probable that it would thrive in any part of the eastern states.

There is in the same issue a figure (672) of the male flowers of *Abies bracteata*, here figured for the first time from a specimen grown in the gardens of Eastnor Castle. This tree, an inhabitant of a few sequestered valleys only, in the very heart of the Santa Lucia Mountains in California, is the most limited in its range as it is one of the handsomest of all the Silver Firs. The long, remarkably broad leaves are very striking, and the cones, with their long exserted bracts, are quite unlike those of any other species. *Abies bracteata* is one of the most tender of all the Firs, and there are only a few sheltered situations in Great Britain and in the south of Europe where it has been found entirely satisfactory. It is, unfortunately, quite tender in all parts of the eastern states where it has yet been tried.

The supplement of the *Gardeners' Chronicle* of the same date represents a magnificent specimen of *Dendrobium Devonianum*, grown at Arddarroch, in Scotland, with 864 flowers. This is considered a difficult plant to manage, and it is rarely seen in collections in good condition. The secret of its successful cultivation seems to consist in growing it on rapidly as soon as the flowers have faded and then giving it a long rest in a cool, airy house, that the deciduous leaves may ripen and fall and the pseudo-bulbs become thoroughly matured.

London Letter.

NEW PLANTS.—In an appendix to the *Kew Bulletin* for June a list is given of all the new plants introduced into cultivation during 1889. Not only English, but Continental and American publications, have been consulted in compiling this list, which is therefore as complete as is possible. In addition to new

petals, which spread to a width of four and a half inches; the sepals are broad, and the lip is formed as in *C. niveum*. The color of the whole flower is pure white, with numerous red spots arranged in lines on the sepals and petals. A plant of it was recently awarded a first-class certificate by the Royal Horticultural Society. Like all the hybrids of which *C. niveum* is one of the parents, *C. Aylingii* is elegant in the form of its flowers and pretty in color. Except in the markings of the flower, there is very little of the character of *C. ciliolare* in the hybrid. I am told that the owner has asked 600 guineas for this hybrid!

Odontoglossum Galcottianum is merely a variety of *O. nebulosum*, differing from the type only in being much smaller in flower and unspotted on the sepals and petals. It was shown here last week as a new plant.

Masdevallia muscosa. The plant at Kew of this exceptionally interesting species flowers freely at least twice a year. It is in bloom now, and its shaggy scapes, curiously formed flowers and highly sensitive labellum attract a good deal of

Fig. 45.—*Ptelea aptera*.—See page 332.

plants brought into cultivation for the first time, all re-introductions of any note are included. A plant may have been in cultivation several years before its introduction is recorded. Such plants as Palms and other foliage plants which do not flower until large, are often well known in gardens under garden names, whilst botanists are unaware of their existence. The Kew list is of special value for the following reasons: Reference is given to the publication in which the plant was first mentioned or described. Besides the natural order and country, a brief description of each plant is given. In every case the plant is cited under its published name, although the name may be doubtfully correct; corrections are, however, given where possible. The name of the garden where the plant was first noted is also stated. It will be seen from this that as a reference list for botanists as well as horticulturists this publication is specially valuable. Similar lists were prepared for 1887 and 1888. The cost of each is only twopence, and the publishers are Eyre & Spottiswoode, Fleet Street, London.

Cypripedium Aylingii is one of the prettiest of hybrids. Its parents are *C. niveum* and *C. ciliolare*, and it was raised in a garden at Enfield. In habit and foliage the plant resembles *C. niveum*, but the flower partakes of the characters of both parents. It has broad, slightly twisted and curved

attention. The species is very rare in cultivation. Botanically it is of the highest interest from its being the only *Masdevallia* in which the character of sensitiveness is known; indeed one might almost say the only Orchid with this character, that mentioned by Darwin as occurring in Australia being practically unknown.

Another of the famous collections of Orchids recently formed in England is about to be sold by auction. I refer to that formed by Mr. F. G. Tautz, at Studley House, Hammersmith. This collection is especially rich in rare *Cypripediums*, *Odontoglossums* and garden Orchids generally. It would appear that Orchids, like horses or pictures or other luxuries, may become too expensive, so that with every collector who goes on with them there are others who tire of them, or find the pace too hot. Whilst the number of large representative collections of Orchids in England is probably decreasing, there are, on the other hand, hundreds of small select collections of recent formation. Some amateurs make a specialty of one or two genera such as *Masdevallia*, *Cypripedium*, *Cattleya* or *Lycaste*, growing all the kinds obtainable. In the interests of horticultural botany, the work of these specialists is valuable from the fact that it is better to do one thing well than to do a dozen indifferently.

Several good varieties of *Hydrangea hortensis* have lately been added to those which for many years have ranked among the most useful of garden plants. The best of the new ones is called *H. rosea*, under which name it has lately been exhibited by the Messrs. Veitch. It appears to be a variety of *H. Japonica* rather than of *H. hortensis*, but the size, compactness and form of the flower-heads resemble those of the last named. Its charm is in its color—a rich blush rose, almost a red. It is by far the most attractive of the *Hydrangeas* grown here. The leaves are broad, with deeply toothed margins, and a soft, deep green, as in *H. Japonica*. As a market plant this variety is certain to become very popular. Another new addition is one called *H. cyanoclada* in some gardens, but which is properly *H. hortensis*, var. *Mandshurica*. It is distinct in having its stems colored purplish and in the flower pedicels being deep rose-red, contrasting prettily with the creamy white of the flowers themselves. *H. stellata flore pleno* is a curiosity rather than a good decorative plant. In the large temperate house at Kew, *Hydrangeas* are a pretty feature at this time of year. The varieties of *H. Japonica* are particularly ornamental, as they form loose, elegant bushes, whilst their flower heads are handsome, though not so massive as those of the *H. hortensis* forms. A variety of the last named known as Dr. Hogg is represented just now by a handsome bush four feet through and bearing dozens of heads of white flowers. *H. Thunbergii*, *H. paniculata*, *H. acuminata* and *H. Lindleyana* are also grown in this house. For covering pillars or clothing a wall there are few better plants than *H. altissima*, oftener called *H. scandens* and almost invariably the plant grown as *Schizophragma hydrangeoides*, the genuine plant of this last named Japanese shrub being scarcely known in English gardens. *H. altissima* is hardy in the warmer parts of England and is a most useful wall creeper.

Clematis Stanleyi. This very interesting plant is showing flower at Kew. Although figured in *Hooker's Icones Plantarum*, t. 589, where it is described as the most beautiful of the genus, it does not appear to have ever been introduced into gardens before now. It is a native of Lower Guinea, Macalisberg, and the Transvaal, where it forms a shrub two to four feet high, more or less caespitose and woody at the base. A correspondent in Barberton describes it as being as handsome and free flowered as *Anemone Japonica*. The flowers are three inches across, and are composed of from four to six broad sepals forming a shallow cup, purple or pinkish in color, with yellow stamens. The heads of fruit are beautifully silvery, "a spray looking not unlike a bunch of ostrich feathers." The leaves are decompound. It is possible that from the high altitude at which this species is found it may prove hardy in England.

The Foxglove as a garden plant is really first rate. Several large beds on the lawn as well as masses in the borders here are simply glorious. If some plant-breeder would take the Foxglove in hand and produce a variety of color in the flowers, what a value this common British hedge-row flower would have in the garden. As it is there are few if any amongst the wealth of herbaceous plants at Kew that can be called superior to the Foxglove as an ornamental garden plant.

Notes on American Plants.

Galax aphylla, which is closely related to the *Shortia galicifolia*, is a reliable little evergreen, a native of the southern states. Its numerous round, heart-shaped, crenately toothed leaves are at first of a bright, shiny green color, but as the season goes on they turn to a rich reddish brown. The naked scape, which is a foot or more high, bears at its summit a spike of pretty white flowers. This spike is about three inches long by a third of an inch thick. It is a plant that needs time to become established before it will show to its best advantage, but it is not difficult to grow in a thin shade and a fine soil.

Thermopsis Caroliniana, one of the Pulse family from the mountains of North Carolina, has its flowers in a long, thick raceme or spike sometimes ten inches long by more than an inch thick. The plant itself is often five feet high and the flowers are of a rich, bright yellow and in shape resemble those of a pea. These large racemes are admirable for cutting. It seems to be perfectly hardy and is a desirable plant for warm, sunny situations.

Phlox amœna, formerly known as *Phlox procumbens*, is with us the last species to flower. It is a native of dry hills and barrens of Virginia, Kentucky and southward; yet it is perfectly hardy in southern Massachusetts. The stems grow from six to eighteen inches high and bear a close sessile cyme of pink-

ish purple, or sometimes white flowers, half an inch wide. It is the more valuable for blooming after the other natives of this genus are out of flower. It does well in any ordinary soil and might be useful on dry banks where few other plants would thrive.

The little one-flowered *Pyrola (Moneses uniflora)*, one of the Heath family, closely resembles a *Pyrola*, except that it has only one flower. The leaves, usually three, are clustered near the base. The flower is one-half to three-quarters of an inch wide, usually white, but sometimes rose colored, and usually nodding on an almost naked stem three to five inches high. It grows in cool woods, usually under Pines. Though somewhat difficult to establish it is well worth a trial. It must have a firm soil in the shade and a mulch of Pine needles about its roots will be beneficial.

Two very interesting Pitcher plants, *Sarracenia flava* (Trumpet Leaf) and *S. Drummondii*, have both flowered. The former is a native of Pine barrens from Florida to North Carolina. Its leaves are trumpet-shaped, large and erect, are often two feet long, and its scape bearing the single flower is about the same height. Its flower is yellow, from three to five inches wide and quite pretty. The latter species is a more southern plant, growing from Florida to the middle of Georgia and westward. Its height is a little more than two feet. The leaf is nearly two feet in length and as beautiful in its variegation at the summit as a flower. The flower, which is single at the end of the naked stalk, is sometimes three inches wide and purple in color. Both species are easily grown in boggy soil, and after being established seem quite hardy. Their beautiful leaves alone would well repay the trouble of establishing them. They must have a wet, sandy or peaty soil and full sunlight. Until well established they should be protected by a mulch of leaves in winter, and even after this they will stand the severe cold better if covered. The covering is not so much to protect them from severe frost as to prevent the thawing and freezing alternately in open weather.

The Lizard's Tail (*Saururus cernuus*) is a perennial herb not uncommon in swamps. It grows a foot or more high and bears a dense spike of fine white flowers which endure for several days. The spike is six inches or more in length by half an inch thick, at the summit of a naked stem, and might be useful for cutting. It thrives in the shade, in any light moist soil.

Thalictrum purpurascens (Purple Meadow Rue) is quite common in parts of southern Massachusetts, where it is frequently found growing on sandy soil with the Tall Meadow Rue of our northern wet meadows. Its most natural location according to Gray's description is "dry uplands and rocky hills." It is a slimmer plant than the common one, with purplish stem and fewer leaves. It is easy of culture, and would, no doubt, thrive in much drier soil than the other species. The delicate purple and white flowers are quite pretty for bouquets, and the purple stalks, which are scarcely hidden by the thin foliage, make it a pretty garden plant.

Calochortus luteus from California is one of the many little beauties of this rich genus. Its usual height is about a foot, bearing one to three erect yellow flowers over an inch wide. A brownish stripe crosses the lower half of each petal, below which it is covered with short but stout yellow beards. It is a good species for cutting and the flowers are unlike most of the yellow sorts. It is intermediate in time of flowering. It needs a fine, light soil, with protection in winter. Another interesting species quite unlike the above is *C. splendens*, which flowers about the same time. This grows two feet high, bearing in succession five to ten large pale purple flowers two inches wide on ample stems for cutting. In some ways it is much like *C. longibarbus*, formerly mentioned, but is not so thrifty a plant in this climate, and few of this genus are, but it cannot fail of being admired by all who see it in flower. It should be treated like the others with protection in winter.

Habenaria fimbriata, one of the Purple Fringed Orchids, is a species that is well worthy of cultivation and has been exported to European dealers in considerable quantities. It is often taken for *H. psycodes*, which it somewhat resembles. But its time of flowering is much earlier, and its spike is smaller, with much larger flowers. The lilac-purple flowers are very showy and endure for many days. It is found in wet meadows and swamps, coming into flower the last of June or early in July. It must have a wet or moist situation, and a thin shade is better. For artificial bogs this plant is very useful and it will thrive in the sun in such wet soil.

Iris Virginica (Slender Blue Flag) is a very slender species a foot and a half high, with long, narrow, grass-like leaves and small violet-blue flowers. It is a native of marshes near the coast from Maine to Virginia. It is not so easy to establish as

our common *I. versicolor*, nor so valuable a plant. It does fairly well in a light soil and sun.

Brodiaea grandiflora is one of the finest of the Brodiaeas, growing from eight to twelve inches high, and bearing an umbel of five to ten large blue flowers an inch wide, with darker stripes. They not only come in succession, but each endures for a long time. The plant shows much more thrift in this climate than most of this genus. The leaves, at the time of flowering, when they are dried up in some species, are as fresh and green as at any season. We suppose it is not hardy without protection in winter. A light loamy soil in the sun should be selected. This species is one of the last to bloom.

Southwick, Mass.

F. H. Horsford.

firm perhaps fifteen years ago. The best system to follow in the cultivation of these plants is that of planting them out, the shoots being trained along wires stretched across the rafters, and as the flowers are pendent and usually produced on long, slender stems, a very pleasing effect may be thus procured.

As regards soil the Tacsonias are not very fastidious, and a good sandy loam, well drained, is sufficient for their needs, though the judgment of the cultivator should always be used in deciding this question of soil, as in some localities the loam may be found too heavy for plants of this character, and the addition of about one-third of peat may prove very beneficial under such circumstances.

A Japanese Pot Plant.—See page 330.

Greenhouse Climbers.

THE genus Tacsonia of the Passion Flower family includes some of the most beautiful and graceful climbing plants in cultivation, and being mostly of easy growth, they deserve more general use in the furnishing of conservatories than has been accorded them, at least on this side of the ocean. The Tacsonias are natives of Central and South America in most instances, though one fine variety, *T. Exoniensis*, is of garden origin, being a hybrid between *T. Van Volxemi* and *T. mollissima*, and was introduced by a London

An intermediate temperature (that is, about fifty-five degrees) is quite warm enough, and thorough syringing is necessary to prevent the inroads of red spider, this pest being very partial to the Tacsonias. Probably the oldest and certainly one of the best examples of this family is one of those already referred to, *T. Van Volxemi*, a native of New Grenada, which has large, bright crimson flowers, very freely produced on a well-established plant, and hanging down on slender footstalks from one foot to eighteen inches in length. These flowers are frequently followed by fruit, which has some slight resemblance to an elongated Green Gage Plum, though without

the stone. The fruits, like many others among the Passifloraceæ, are edible, though not specially pleasant in flavor.

Tacsonia Exoniensis is also a very handsome sort, and resembles the preceding in foliage and habit, but the flowers are of a different shade, being inclined to magenta. It is also a good grower and the flowers hang down in the same graceful manner as those of *T. Van Volxemi*.

T. Buchananii is another excellent species, and produces large and showy bright scarlet flowers in great profusion after the plant has attained considerable size.

It is rather a rampant grower and is consequently not so well adapted for planting in a small conservatory as the varieties above mentioned, but where sufficient space can be given for its full development it will prove a remarkably effective creeper. It has large, dark green leaves, which are somewhat tomentose, and divided into three or five lobes, and reminds one quite strongly of some of the strong-growing Passifloras; in fact, this plant has also been named *Passiflora vitifolia* in some catalogues.

The Tacsonias are easily reproduced by means of cuttings or by seeds when the latter are procurable, but cuttings of moderately soft wood and two or three joints in length are readily rooted in a propagating frame. The advantage of using cuttings of three joints in length is found in the fact that they often start away quicker than those which are made with only one or two eyes, as the latter sometimes fail to start on account of the buds being defective.

Stigmaphyllon ciliatum is an admirable summer-flowering creeper from Brazil that deserves a much wider distribution than it has yet received. It is a rather slender-growing plant with medium-sized cordate leaves of a grayish-green color and ciliated around the margins. The flowers are produced in rapid succession along the stems and last for a considerable time, being of peculiar form and orange-yellow in color. This plant used to be considered a proper subject for stove treatment, but of late years it has been found that it flourishes in an average greenhouse temperature, and in fact it has proved a beautiful addition to the out-door climbers, at least as far north as Washington, District of Columbia. I saw at the Botanic Garden in that city some years ago a plant against a fence, over which it ran wild, and being well clothed with its bright blossoms, was a truly charming sight. *Stigmaphyllon* is also propagated by cuttings, and will flourish under similar general treatment to that recommended for Tacsonias.

Holmesburg, Pa.

W. H. Taplin.

Notes on Shrubs.

ONE of the most useful and valuable shrubby plants for use as an undershrub in waste places, or on embankments where not too sterile and dry, is our native *Rubus odoratus*, better known as the Purple Flowering Raspberry, or in some districts as the Thimbleberry. The last popular name, however, is more properly applied to the Black Cap or Black Raspberry (*R. occidentalis*). The Purple Flowering Raspberry is more suited to be planted in free places, where it may spread, than it is in small well-trimmed garden-beds or shrubberies, because of its habit of spreading from the roots and occupying much ground to the exclusion of lower and less robust vegetation. The foliage, although not of such a handsome green as that of some other equally hardy plants, is yet very attractive by its large size and density, and also for being usually little injured by leaf-eating insects. This plant is naturally at home in hilly districts or further north, where it delights in more or less stony, but fertile, soils. The fruit is usually considered almost worthless, yet it is often of quite a pleasant but peculiar flavor, and in some parts of Canada is sometimes collected and sold by the habitants. But it is so thin and flat, and so soft when fully ripe, that collecting it is not profitable, and it does not bear keeping or much handling. In cultivation here it is usually after the middle of June before the large, handsome, purple flowers appear, and the plants continue to bear some flowers even after the fruit begins to ripen early in August.

The first flowers of this species, however, are preceded two or three weeks by those of the White Flowering Raspberry (*R. Nutkanus*), which is found at home from northern Michigan westward through the Rocky Mountains. Although a native of pretty high latitudes, this species has not been hardy enough at the Arboretum to withstand the cold of our winters when growing side by side with the Purple Flowering Raspberry. Owing to a mild winter and careful covering, the stems were not killed last season, and flowers have been freely produced for the first time. It is possible that the lack of hardiness may be obviated by procuring seed from the ex-

treme northern limits or most severe climate where the plant grows naturally. The seed of those in the Arboretum was collected in Washington Territory. In most of its characters this species is almost equal to a white *R. odoratus*. The silky white petals are not quite so large and long, but the flowers expand from an inch to an inch and a half across. They have a sweeter and more delicate fragrance than the purple flowered species, and, as in the latter, a pleasant resinous quality, which, emanating from the sticky glandular hairs covering the young shoots and sepals, is mingled with the odor of the flowers.

The beautiful white flowered Rocky Mountain Bramble (*Rubus deliciosus*) chiefly differs in habit from both of the preceding species in not spreading over the ground by new shoots from its roots. It is perfectly hardy when growing beside the more tender *R. Nutkanus*, which it far surpasses in beauty of blossom. The flowers are flat and about two inches across, and are usually mistaken for large Wild Roses or the Cherokee Rose by people who have seen the latter. The odor of the blossoms is slight and rather pleasant, although it has been happily compared with the smell of bleaching cotton. It is an early flowering species, and here it is usually in its finest condition of bloom about the twentieth of May. In warm situations the first blossoms appear in the first week of the month. The plants in this region do not appear to produce much fruit, and that only rarely. As they do not spread by suckers or great enlargement from the original shoots they are not easily propagated by root division; and cuttings from the wood do not readily form roots and grow; nevertheless the last is the best method of increasing the stock, unless it is by seed.

Few trailing plants combine a prettier effect of foliage and flower than the Running Swamp Blackberry (*Rubus hispidus*) when in good condition. Although its common name suggests wet places as its natural haunts, it will grow well in any good garden soil, and is especially valuable for planting in rockeries. The flowers are borne throughout most of the month of June. They are effectively set off by the dark evergreen looking foliage, which has an added value in the bright colors assumed in autumn.

The Dewberry (*Rubus Canadensis*) often makes a pretty covering over the ground, but the leaves are not of such a handsome dark green as those of the last species. The Dewberry was long neglected by horticulturists, and has only within a very few years received much attention as a fruit-bearing plant. In a wild state the fruit is very variable in size and flavor, but by selection and under cultivation it is possible to produce berries which, for size and flavor, cannot be distinguished from some of the best blackberries.

The earliest ripe fruit on any of the genus is that borne by the herbaceous Dwarf Raspberry (*R. triflorus*), which in cultivation ripens the first of its amber-colored berries before the middle of June. The fruit is small and of a pleasant acid flavor, but is not abundant. This species, though pretty and delicate, has no peculiar characters which make it of much ornamental or economic value. In flower, foliage and fruit it appears to have closer affinities with the Blackberries than the true Raspberries.

Arnold Arboretum.

J. G. J.

The Rock Garden.

A BLUE variety of *Viola cornuta*, known as Perfection, and the white variety, Alba, are being extensively used this season by landscape-gardeners in the vicinity of Boston for summer bedding. These Violets are intended to supplement the blue and white *Lobelia erinus*, which seldom blooms well during wet seasons. Both are free and persistent bloomers, and being quite hardy are fit subjects for the rock garden. Rock Roses, *Helianthemum vulgare* and its varieties, are, if not exactly showy, very pretty and interesting. These are easily propagated, either from hard wood cuttings placed in a cool frame in the fall, or soft cuttings in propagating-beds during spring. *Campanula Carpatica* in variety, and *C. rotundifolia*, the true Bluebell of Scotland, are well established with us, sowing themselves freely, and needing to be carefully thinned out to prevent their becoming weedy. *Geranium sanguineum*, bright purple, and *G. Endressi*, bright pink, are the hardiest and best of all these kinds to grow, inasmuch as they take care of themselves, and continue well in bloom throughout the summer.

The double *Lychnis vespertina* is a very old-fashioned plant. It is not common, however, being rather hard to propagate. It can best be increased by cuttings, as the root-stock does not bear division. It is very difficult to get anything but flowering stems for cuttings, and these root very slowly and take a long time to make plants. It is, however, a very desirable plant.

The flowers are of the purest white, excellent for bouquets, and last a long time when cut. The habit of the plant is decumbent, fitting it either for the rock-garden or border, and it produces bloom from June until October. I was surprised to find *Erodium Manescavi* survive even a mild winter. It is now nicely in bloom, and will continue through the summer. Though not particularly showy, it is yet the brightest of the genus, and combines with its rosy flowers handsome fern-like foliage. This can be increased easily by seeds or by division of the root-stock.

Genista tinctoria (Woad-wax) is a pretty, dwarf, prostrate, leguminous shrub of great merit, being an ideal rock-plant, and at the same time excellent for cutting purposes. Hardwood cuttings taken in the fall, and wintered in a cool frame, root freely in spring. Thousands could be raised in this way in a comparatively short time, and no plant, it seems to me, would be better for covering sunny banks and planting on natural ledges, where they occur on estates. A companion to this is *G. sagittalis*, a very distinct and showy species, which has phylloidal stems and bract-like appendages, taking the place of leaves, and performing their functions.

Among Sea Pinks (*Armeria Lauchiana*), known also as Crimson Gem and Pink Beauty, is the best. Though old and common plants, they are great favorites everywhere, never being untidy, for when not in bloom their persistent green leaves always look pleasing. *Silene alpestris* has flowered remarkably well this season. A mass with its elegant star-shaped flowers of the purest white is quite striking. *Achillea tomentosa* is one of the few species of this genus which is not weedy. The flower-heads are a good clear yellow, not over one foot tall. The foliage makes a good green carpet. The Alpine Bugloss (*Ajuga alpina*) is a common species, and the most attractive of the genus, having whorled spikes of lovely gentian blue. It should not, however, be planted in a choice position on account of its liability to overrun smaller neighbors. The path leading to our rock garden takes a zigzag turn through the Ghent Azalea bed. This path is lined on either side with *Myosotis palustris semperflorens*. This Forget-me-not is equally at home in sun or shade, and would make an excellent plant for covering the ground in shrubberies did it not so entirely take possession of the soil wherever planted.

Wellesley, Mass.

Notes and Queries on Hardy Plants.

Inula glandulosa is a plant that has been known to gardens about fifty years and is still as scarce as it is beautiful. There is no reason why this should be so, except, perhaps, that it is not sufficiently known. The plant in question is a Composite with bright orange-yellow flowers three or four inches across on stout erect stems two feet high. The flowers have large discs and numerous narrow ray florets and are very ornamental. There is nothing coarse or weedy about *I. glandulosa* as in the native species *I. Helenium*, and it is just possible that the influence of the latter has been prejudicial to the former amongst cultivators of hardy plants. I recently saw a fine *Inula*, which I think was called *I. grandiflora*, but whether a species or a variety of the above I do not know. As the seed came from Herr Max Leichtlin, perhaps he can tell us more of the plant. Certain it is that it is one of the best novelties I have seen lately, and the plant is most promising, as it is easily raised from seed, has bright orange flowers and is perfectly hardy here in Massachusetts.

And now as to *Delphinium Zalil* (*sulfureum*). Mr. Farquhar, of Boston, tells me he saw it at Erfurt last summer fully five feet high, with much branched stems, covered with beautiful lemon-yellow flowers. If this can be done in Erfurt, why not here? Should the plant be biennial or perennial it certainly would be worth growing. I have seen but one lot of plants, and they were about eighteen inches high when about to bloom and much resembled *D. Chinensis* in habit. My own attempts to raise this *Delphinium* from seed have been failures.

Nor have I succeeded with *Ostrowskya magnifica*, another novelty, the figures of which in English papers raise one's expectations. Nothing is better calculated to cool one's ardor than sowing seed and waiting for plants that never come. It is quite possible that there is no difficulty about obtaining the above plants from seed, if we only knew the conditions necessary, whatever they may be. It appears that good plants of *Ostrowskya magnifica* have thick, exceedingly brittle roots that are often four feet long, so it is obvious, if we are to have them at all, seed is the least difficult way to get them, if it would only germinate.

South Lancaster, Mass.

Oilcake for Wire-worms.—When pasture land is taken into a garden, there is usually trouble from wire-worms. A Primrose bed at Wisley was much injured by them. A good gardener told me that if bits of oilcake were sunk in the ground, the wire-worms would eat it, and a great gardening authority said that it killed them. My gardener put a number in a box with some cake, but so far they seem none the worse, but it is a most effectual trap. Pieces about the size of a hen's egg sunk three inches in the earth, with a stick to mark the place, and taken up after three or four days, will be found to have wire-worms imbedded in them, eight to twelve to a piece of cake. We have killed many hundreds. Old stagers know the use of oilcake, and gas-lime is said to be effectual, but with plants in the bed this would be dangerous.

George F. Wilson, in *The Garden*.

[Why not poison the oilcake? In this country, where a dough of sweetened corn-meal is used as a bait, it is poisoned; and arsenites sprinkled on fresh leaves of clover or elder and laid about a field or garden under boards have proved effective.—Ed.]

The Forest.

Notes on the Ligneous Vegetation of the Sierra Madre of Nuevo Leon.—I.

THE Andean Mountain system, continued through Central America, forks in the Mexican state of Oaxaca, the principal or longer branch running on northward parallel with the coast of the Pacific Ocean and the Gulf of California, and not far inland, and the shorter though not less elevated branch diverging northward (precisely speaking north by west), and terminating in the scattered mountains of south-western Texas. Within these two giant arms is embraced the high table-land of Mexico. To the loftier summits, the central backbone of both these mountain chains, is applied the name of Sierra Madre, or Mother Range, the flanking ranges and outlying spurs more or less separated from it by inhabited valleys receiving special names. For some two hundred miles of its extent the eastern Sierra Madre chain is included within the state of Nuevo Leon, or forms the boundary between this state and the state of Coahuila on its west.

Several months of the summers of 1888 and 1889 were devoted by me to attempts to explore this Sierra Madre region with base during most of the time at Monterey—Monterey aptly named, the word telling of the kingly mountains which tower round about this quiet city of white, sunny streets and green, shady parks and gardens; to the eastward Sierra de la Silla, or the Saddle Mountain, with its grotesque sky line only four miles away and 4,000 feet above the plane of the city; on the west the Mitre Mountain, terminating in towers and sharp pinnacles of bare rock, quite as lofty and quite as near; while on the south at scarcely less distance are miles of the Sierra Madre stretching east and west even higher, a bare mountain wall of soft, white lime rock, lichen-stained, terminating in a thin comb, on whose crest are seen waving a few scattered Pines and Palms. The northern face of this mountain wall it is not possible for the foot of man to scale, but we pass around it at either end through cañons plowed out in the soft lime rock by the torrents of countless summers—cañons with vertical walls often hundreds of feet high—and mount by these with severe toil to wooded slopes and summits, only to see higher and higher summits beyond and above us, and to find too often our further advance rendered perilous or impossible by a network of forking cañons.

Across this Sierra Madre range the traveler by train of the Mexican National Railroad between Monterey and Saltillo is borne almost as swiftly and gently as though by the enchanted tapestry of the Arabian Nights. Looking backward and away to the south-east as the train mounts the mesas of Garcia and nears the base of the mountains, he sees several successive ranges with serrated summits rising one above the other and receding far away in the soft blue haze. Soon after passing Garcia station, twenty miles west of Monterey, the train enters a labyrinth of

deep cañons. Slowly and laboriously the engine pants in dragging the train up the hard grades. On every hand, as the train winds through the cañons and crosses their rivulets from side to side, arise steep mountains, their brows 1,000 to 2,000 feet above the road. In their configuration, in their formation, and in the vegetation which they bear, these mountains afford a good illustration of the arid mountains which dot or rather line off at intervals the broad northern table-land covered by the states of Chihuahua, Coahuila and Durango, and parts of Zacatecas and San Luis Potosí—limestone of various qualities showing more or less quartz, its strata contorted in the wildest manner, scarcely half concealed beneath a thin covering of soil which is barely sufficient to support a low dingy green growth of Agaves, Cactuses and desert shrubs. Only in rare places where there has been an accumulation of soil, as in cañon pockets and in hollows about the summits, are seen a few clumps of small trees.

Some thirty miles from Garcia and 3,000 feet above that place the train emerges upon the open table-land, and turning southward skirts for a long distance the western base of the Sierra Madre.

Thus we gain some idea of the character of this mountain chain, which stands with its western base resting upon the inland plains 6,000 feet above the sea, and its eastern base upon the lowlands only 1,500 feet in elevation. From central summits 10,000 feet high its western slope descends gradually by comparatively broad ridges and open valleys, while its eastern is steep and everywhere cut by the most terrific cañons. On its eastern slope and along that base fall the rains which come up from the Gulf of Mexico; and living springs and streams abound there, which condition ensures perennial verdure and considerable forest-growths. Its western slope, on the contrary, being left rainless during most of the year, partakes, as we have seen, of the character of the desert mountains of the interior; rarely are springs or brooks to be found there; and forests are mainly confined to the higher and cooler summits, or to those situations which are least exposed to the sun. Furthermore, the floras of the two sides of this Sierra Madre are quite different, not only as respects woody plants, as will be seen, but herbaceous as well.

To mention (though quite incidentally, because the district lies within the state of Coahuila, yet for purpose of comparison) the ligneous species observed on the mountains about Carneros Pass, on the western side, I may begin with *Pinus cembroides*, because this species appeared to be the one most abundant and widely dispersed. As a small tree, seldom more than twelve or fifteen inches in diameter, low-headed by reason of its sparse growth in the shallow dry soil of the region, it occupies the cooler slopes and summits of the foot-hills, coming down within a few hundred feet of the level of the plains.

Pinus latisquama, growing with it, and choosing especially the dry calcareous bluffs of gulches, is a much smaller tree, is less than a foot in diameter and less than twenty feet high. Its long horizontal branches, with long and slender branchlets bearing tufts of bluish green leaves from which hang on long peduncles the solid and heavy cones, give this tree a peculiar appearance among Pines.

Widely distributed, also, and at various elevations, appears *Quercus grisea*, here more than ever a slow-growing, gnarled, contorted tree, its trunk, even its branches, showing hollows and seams.

About the margins of the higher plains and valleys, where these rise by gentle slopes to meet the foot-hills and fill the recesses amongst them, thin forests of *Yucca Treculiana* lend a striking character to the landscape. The stems of this plant, rather less than a foot thick, rise to a height of fifteen to twenty feet, and bear single heads (or at most but few heads on short branches) of numerous sword-shaped leaves about two feet long. The panicle of flowers is three feet in length and erect; but it appears to be rarely produced here.

On the higher summits a third Pine was met with, pre-

sumed to be the tree doubtfully referred by Mr. Watson (Parry & Palmer, 844) to *P. Teocote*. It forms a large tree, similar in appearance to *P. Montezumae*, and yields much good lumber.

The more shaded and cooler slopes of the higher mountains, especially the ravines with northern aspect, which furrow them, bear dark groves and belts of *Pseudotsuga taxifolia*. With this tree, but following the ravines down toward the base of the mountains, is *Cupressus Guadalupeensis*; while *Juniperus flaccida* and *J. tetragona*, var. *oligosperma*, small trees less than a foot in diameter, were found in cañons near their base.

The sunnier and therefore drier slopes of these mountains are covered with a dense growth of shrubs, chiefly Oaks, *Quercus reliculata*, and another, perhaps a new species near *Q. pungens*. In rich cañons the former becomes a tree as elsewhere, and with it are *Q. Emoryi* and *Q. virens*.

The foot-hills are mainly ledges of limestone scantily strewn with soil, and these bear, besides the usual growth of Cactuses, Agaves, etc., a scanty shrubby vegetation composed chiefly of the following species: *Lindleya mespiloides*, in gulches growing to a height of ten to fifteen feet; *Cercocarpus parvifolius*, inferior growths; *Cowania plicata*, a lovely plant when covered with its Rose-like flowers; *Fraxinus Greggii*, with slender stems fifteen feet high and forming thickets; *Arbutus Xalapensis*, in a dwarf state; *Arctostaphylos pungens*, *Microrhamnus ericoides*, *Rhus microphylla*, *Ceanothus Greggii* and *Ephedra aspera*, sometimes six feet high.

C. G. Pringle.

Periodical Literature.

Under the title "Lungs for our Great Cities," the Earl of Meath, who has had experience in such matters, as Chairman of the Metropolitan Gardens Association of London, gives, in the *New Review* for May, an account of the impressions he received during a visit to the chief cities of this country. "A veritable rage for park-making," he says, "seems to have seized the American public. The large towns of the United States and Canada are vieing with each other in the establishment of parks and boulevards. Taxation for these purposes is readily submitted to, and enormous sums of money are now being annually voted on this account."

At Chicago, he was told not only that the Park Tax was the one to which no objection was ever made, but also that officials were constantly being asked why more money was not spent on the parks, "as it was the one expenditure of public money which the people thoroughly appreciated, enjoyed and took pride in." But the author says it is only within recent years that the necessity for having breathing spaces in cities has thus been recognized; so, in our older towns, the more densely populated districts are devoid of those frequent small parks, which alone can give the poorest of the poor a daily breath of fresh air and sight of green leaves. It is with great approval, therefore, that he notes the recent passage by the Legislature of an act for the incorporation and improvement of additional parks in the City of New York, and the appropriation for the purpose of \$10,000,000, to be expended in ten years. We wish we could feel as confident as he seems to feel that within this time the whole sum will indeed be spent in pulling down tenement houses, and purchasing sites for numerous small playgrounds. The park areas of many towns, from Boston to San Francisco, are passed in review by Lord Meath, with few words of criticism and many of high approval. Druid Park, in Baltimore, he calls "in some particulars the finest park among those I visited—a lovely specimen of the forest park." Fairmount Park, with the ravine along the Wissahickon River, he says is second in size among the public pleasure grounds of the world, to Epping Forest, near London, only, and, "perhaps, in its particular type of beauty, is second to none." He speaks of the Central Park as extremely artificial, but adds, "notwithstanding this excessive artificiality, Central Park remains one of the most beautiful of gardenesque places. I know nothing prettier of its kind than the view I saw on an October day, standing on the 'terrace,' at the end of the 'mall,' in the Central Park, looking across the artificial lake to the opposite shore, blazing in the glorious colors of American autumn foliage. The finest natural parks, as opposed to artificially-made grounds, in the United States, are, perhaps, those of Druid Hill, Baltimore; Fairmount Park, Philadelphia; Prospect Park, Brooklyn; and Forest Hill, St.

Louis; whilst among the artificial parks, Central Park, New York; and Lincoln and South Parks, Chicago, may be said to rank highest. These two cities have both had to manufacture recreation grounds out of the most unpromising materials. They have had to transport for long distances the actual soil of which their parks are composed, and have had to plant every single tree, shrub and flower within their limits, and make every rise and depression of the ground. These gardens are, consequently, entirely different in style from those magnificent parks which owe their beauty and picturesqueness to nature, and they must be viewed with a different eye, and be judged by a different standard." There is some mistake as regards the Central Park in this description of the difficulties which attended its making. With the exception of two or three ancient Oaks and Willows, there are, indeed, no trees in its lower portion which were not planted, but in the northerly portions there are many of native growth; and here, instead of making rises and depressions in the ground, the landscape-gardener's task was to level some of those which already existed in too great numbers, in order that certain broad, quiet, practically level stretches might be secured. But this means, of course, that the task was even more difficult than the English critic suggests. Again, in distinguishing some of our parks as natural, and others as artificial, Lord Meath does not use the terms exactly as a landscape-gardener would use them. The Central Park, with the exception of one or two features, like the Mall, is distinctly in the naturalistic, not the artificial style. In certain parts, as in the ravine toward the northern end, where the Rhododendrons grow in masses, it looks as though man had done no more than lay out the needful roads, while in other parts, like the sheep-meadow, which was actually formed by blasting out surface irregularities, it looks as though he had merely refined upon and carefully tended a spot which nature had created much in its present shape. What the author really means by the contrast he draws is that some of our parks look wild and others cultivated—some look like untouched natural scenes, and others like natural parks in the technical acceptance of the term.

But, throughout the article, Lord Meath shows that his concern with parks is practical, rather than artistic. He thinks, or, at least, speaks little of their design and much of their position and the facilities they offer for the recreation of the people. In many directions, he finds them better adapted to this end than English parks. Incidentally, indeed, he says that he hopes the wildness of the new parks in our "annexed districts," as compared with the "artificiality"—that is, the true park-like character—of the Central Park, "will, perhaps, encourage New Yorkers to give a little more latitude and freedom to the citizens in the use of their parks." But he may not have remembered, in contrasting London customs with ours, that the greater heat and dryness of our summers render it imperative to limit access to the meadows, if the grass is to be preserved at all; and he does full justice to the facilities afforded for sports in various parts of the Central Park. As he seems to have been here in the autumn, he doubtless missed one of the most delightful scenes that this park offers—a Saturday afternoon in June, when all the greens are freely given over to the school children, and they swarm in thousands everywhere.

In general, Lord Meath speaks with unstinted praise of the way in which American parks are made useful to the people, as well as pleasant in their eyes. From this point of view—as true recreation grounds—he finds in them many arrangements that might advantageously be imitated in England. In London, he says, there is no zoological garden freely open to the public; the small parks are not lighted so that they can be used in the evenings; the children have no swings, merry-go-rounds and goat-carts; nor do our conservatories, our music-galleries and our numerous facilities for athletic sports find a parallel there. Even the "Lohengrin boats," which many of us think grotesque, rather than ornamental, come in for a share of his generously-bestowed praise. The provisions for athletic sports in the Charles River Embankment Park, in Boston, are described at length, and with the highest approval. Moreover, the way in which our parks are managed by small boards of commissioners, "independent and comparatively permanent," he finds much better than the English plan of a large council elected by a popular vote which, in London, cannot undertake "any expenditure exceeding the sum of £50 without a vote and discussion in full council of 137 members." It is cheering to get a word of praise for any municipal arrangement in this city, which we have come to consider as by no means the best governed in the world! The power our Park Commissioners possess to control the

thoroughfares, and, in some cases, the building sites in the neighborhood of the parks, is likewise commended. The object of Lord Meath in making the extensive journey whose results he here describes was "not to criticise and find fault, but, if possible, to learn, with a view to the improvement of the London parks," at that time under his charge. Undoubtedly, had his aim been different, he could have found many details to criticise; but it will be a surprise, we think, to most Americans to learn how many things he found, from his own point of view, that were worthy of imitation. In some ways, Americans are conceited enough; but as regards all matters of municipal administration they are very apt to think that "they order these things better in France," and in every other part of Europe, too. Many travelers, seeing the free way in which Londoners are allowed to walk on the grass in their parks, come home to say that the pleasure of the people is better considered there than here. Nothing could be more useful in opening their eyes to the real facts of the case than this clear and comprehensive article of Lord Meath's. Nor will it fail to surprise many by its mere enumeration of the number and extent of American parks, and its account of the zeal and discretion with which they are being enlarged and improved.

Correspondence.

Hardiness of Indian Azaleas.

To the Editor of GARDEN AND FOREST:

Sir.—Your note on the Indian Azaleas in Central Park reminds me that I had a fine plant of the variety known as Alba, and grew it for years with no suspicion that it was hardy until ten or fifteen years ago I discovered it by accident. My plant stands by the porch on the east side of the house, and during the ten or twelve years since it has been there it has failed to flower but once, and then a cold wave late in the spring swept down upon us and killed the buds, just as the March weather killed all the Peach-buds this year. My plant is of oblong shape and nearly five feet through the longest way. It was covered with bloom this spring, and judging from the exclamation of the occupants of the hundreds of carriages which passed by, it must have seemed to them, as it certainly did to me, a strikingly beautiful object.

Montclair, N. J.

E. Williams.

Forestry and Irrigation.

To the Editor of GARDEN AND FOREST:

Sir.—The reason that more attention has not been given to the articles on Institutions for the Arid Lands, in the *Century Magazine*, is partly in the fantastic element in them, the quality of unreality, as in the passage which affirms, regarding the people of those regions, that "on this round globe, and in all the centuries of human history, there has never before been such a people. Their love of liberty is unbounded, their obedience to law unparalleled, and their reverence for justice profound; every man is a freeman king with power to rule himself, and they may be trusted with their own interests." It is encouraging to hear of the superior civilization of our fellow-citizens of the far west. I have long been aware of their many good qualities, but had not known before that absolutely no other people equaled them in obedience to law. It seems queer that among such people there should be "a bitter, relentless war, disastrous to both parties," between capital and labor, and that many farming corporations and water corporations have been almost destroyed by unfriendly legislation and by judicial decision, as we are informed a little farther on in the same article. The information that "when the physical powers of nature are employed, and human powers engaged in their control, men cannot be enslaved; they assert their liberty and despotism falls," is curious, and if true may be important. Is there any evidence in all Major Powell's writings that he has ever studied forestry subjects? Did he not rather begin by inventing theories of his own which have no basis in the observation and comparison of phenomena? The indifference to the facts upon which forestry is founded is palpable in all his later writings that I have seen. And as to feeling, a man with much feeling for trees would not set fire to a grand forest, or even to one noble tree, and then constantly tell of it with so much zest. Whatever may be the reason, Major Powell's voice has not been heard in recent years in aid or encouragement of the friends of the forests, but in opposition to their efforts.

Washington, D. C.

L. W.

Notes.

Remarkably fine Nectarines from Jobstown, New Jersey, have been selling in this city at from four to six dollars a dozen.

Local journals state that Pecan-nuts have recently come for the first time into the markets of Vienna. They were called by their introducers "Indian nuts," but, their origin being unknown to the public, the term has quickly become corrupted into "India nuts."

Within the past ten years the park area of this city has increased from 1,094 to 5,000 acres. Of course, most of the increase is included in the so-called "annexed district," where the parks, although containing beautiful passages of natural scenery, have not yet been definitely treated by the landscape-gardener.

The large Japanese Lilac, *Syringa Japonica*, never flowered as well as it has this year, which seems to indicate that the tree will improve in its flowering qualities as it grows older. The creamy white inflorescence is so large that it makes a good show at a distance above the deep green leaves, and this fact also adds to its value.

According to the *Revue Horticole* the best new Rose of the year which has appeared in Paris is the variety on which has been bestowed the somewhat cumbersome name of La France de 1889. It is a seedling from La France with flowers equal in size to those of Paul Neyron. The color of the flowers is described as a soft rose-magenta, and they reach even on the young plants a diameter of six inches.

In our London letter, on another page, Mr. Watson has a good word for the Foxglove as a garden plant in England. It is strange that this flower is not more generally used in American gardens. Nothing can be more effective than the tall spikes of the Foxglove at a little distance when scattered singly or in small groups with a background of shrubbery or dark foliage. A close inspection, too, will show that the individual flowers are not only beautiful in form, but exquisitely delicate in their color markings.

The "bent wood" furniture exported in such quantities from Austria is manufactured from the wood of the Beech, which, after being sawed into long strips, is turned into round rods. These, on exposure to the action of superheated steam in an air-tight case, become so pliable that they can be bent by hand to the iron patterns. The drying occupies several days, after which but little labor is needed to combine the pieces into articles of furniture. Almost the only rocking-chairs one ever sees in Europe are made of this "bent wood."

No Azalea is more beautiful than *Rhododendron (Azalea) arborescens*, which is at home along the smaller streams among the foot-hills of the North Carolina mountains, and which has been figured already in this journal (i. 140, fig. 64). The pure white flowers are not viscid like those of our Swamp Honeysuckle (*R. viscosum*), and the bright scarlet stamens and pistil add much to their attractiveness. Their fragrance, too, is delightful, and the leaves when drying exhale the perfume of new-mown hay. The plant comes into bloom later than other Azaleas, and this year the flowers in the neighborhood of this city lasted until the 4th of July.

The principal illustration of the *Revue Horticole* of the 16th of June is devoted to a group of single Chrysanthemums to the beauty of which Monsieur André calls especial attention. These charming flowers, which possess ornamental qualities of the highest class, have been very much neglected in this country in the rage for the double-flowered varieties which have become so fashionable of late years. A single Chrysanthemum flower cannot, of course, be compared in any way with one of the great double flowers. They are very beautiful, however, and add so much to the variety of a collection that it is surprising they are not more frequently cultivated.

We have more than once spoken of *Fraxinella (Dictamnus Fraxinella)* as an old-fashioned garden plant, now almost forgotten, which should again become popular on account of the delicious fragrance of its flowers and their property of emitting a volatile oil in such quantities that it may sometimes be ignited by a match even if held at a little distance. The *Illustrirte Garten Zeitung*, of Vienna, recently called attention to the same facts, saying that the plant had actually been regarded by some in former times as the "burning bush" of Moses. It grows wild in the Austrian Alps, where in rocky woodland nooks it attains a height of more than three feet; and the writer in question takes it as a text to plead the cause of the many indigenous plants which, it seems, in Europe as well as in America, are ignored in favor of foreigners no whit more beautiful than they.

According to a note in the June issue of the *Revue de l'Horticulture Belge et Etrangère*, there is in the gardens of the palace at Versailles an Orange-tree more than 450 years old. It is said to have been the first introduced into France, and is known as the "Grand Connétable." The seeds from which it grew were sown at Pampelune about 1416 by Eléonor of Castile, wife of Charles the Third, King in Navarre. Later the tree was brought to Chantilly, then to Fontainebleau, and finally, in 1684, was added to the collection of Versailles. The handsomest Orange-trees, grown in tubs in France, are those in this collection and in those of the gardens of the Tuileries, and of the Luxembourg Palace in Paris. The gardens of the Palace of Compiègne still contain fifty large specimens, brought there during the reign of Napoleon I. There are also collections of these curious old Orange-trees supposed to be several centuries old in a number of private gardens belonging to various French chateaus. They are always carefully tended, and produce year after year surprising crops of flowers and a good deal of fruit, considering how long their roots have been cramped within narrow quarters.

Mr. Barr Ferree, writing in the *American Architect and Building News*, describes an interesting bit of Aztec construction, the dome of a building called the Sondorhuasi, at Azangaro, in Peru. An ancient Spanish historian, writing of such roofs, says they "are of straw, but so artfully laid on that, unless destroyed by fire, they will last many ages." This verdict is certainly justified by the roof in question, which is still in good condition, although known to have stood for more than 300 years. It "is formed of Bamboos of equal size and taper, the larger end resting on the top of the walls. They are bent to a central point over a series of graduated hoops also of Bamboo. At the points of intersection the vertical and horizontal Bamboos are bound by fine cords of delicately braided grass. On this skeleton is a fine mat of the braided epidermis of Bamboo or rattan without seams, which may have been braided in position. It is worked in colors and panels conforming with the spaces between the framework, which is itself painted. An open and coarse matting fastened with a fleece of finest ichu, depending like a heavy fringe outside the walls, is placed over this. Then comes a transverse layer of coarse grass or reeds, then ichu and so on, the whole forming a slightly flattened cone. The projecting ends of the ichu layers were cut off sharply and regularly, producing the effect of overlapping tiles."

The answer recently given in the Boston *Transcript* to a correspondent who had asked, "What are the legal rights of owners of trees abutting streets and sidewalks?" may be of interest to others, as there is a general belief that these rights are narrower than is actually the case. According to the *Transcript*, in the state of Massachusetts at least, "a street is simply a strip of land set aside for the common good—a highway over which every one has a right to pass. But the public does not own it; it has simply the right of way over it. The fee usually belongs to the owners of the abutting land, who have a right to make any use of the land within the limits of the street which does not interfere with the public's right of way; for instance, the owner of the fee may cut the grass growing by the roadside, gather the fruit growing upon trees within the limits of the highway—the trees are his property. For public convenience towns and cities are required to keep all public highways within their limits in a condition that shall insure the safety and convenience of people lawfully traveling thereon. Cities and towns have no further rights or authority in the streets and highways than simply to discharge the duty imposed upon them by law to make and keep in repair the surface of the street and to remove anything which obstructs travel or renders it unsafe." A passage from the public statutes is then cited which declares that municipal officers may grant permission to retain or to plant trees on the highways in proper positions, that they shall be considered the private property of those who plant them, but that if complained of and proved to be nuisances their removal at the owner's expense may be ordered. In 1867 a suit was brought against a superintendent of streets in Bristol County for allowing the branches of a tree on the highway abutting the plaintiff's land to be cut to permit the moving of an engine-house. The verdict was given for the plaintiff, and the Court remarked, "This enactment has limited in an important manner the powers of highway surveyors. Shade trees are no longer liable to be treated as a nuisance and lopped or cut down at the discretion of every such officer. They are private property, to the ornament and shelter of which the owner of an adjacent estate is entitled, and they cannot be interfered with except upon due process of law, as marked out in the statute."

Can the Nation Protect Its Own Property ?

A FORTNIGHT ago the Senate of the United States, in Committee of the Whole, was considering a bill which provides that "any person who shall maliciously or negligently and carelessly set on fire any woods, underbrush or prairie on any of the public lands of the United States, or who shall suffer any fire, which he may have lighted on other lands, to pass therefrom to the public lands of the United States, shall be deemed guilty of a misdemeanor, and, upon conviction thereof in any District Court of the United States having jurisdiction of the same, shall be fined in a sum not more than three times the value of the trees or other growth so destroyed or injured, or imprisoned for a term not more than three years, or both."

The occasion for framing this measure, as reported by the Committee on Agriculture and Forestry, was found in a message of the President transmitting a letter from the Secretary of the Interior. In this letter it was stated among other things that a fire was started by the Sheriff of Boise County, Idaho, and certain well known citizens with him, which destroyed a large amount of timber belonging to the Government. In accordance with a special agent's report setting forth these facts, it was recommended by the Secretary of the Interior that the United States District Attorney should institute criminal proceedings against the men who kindled the fire. The United States District Attorney returned the papers in the case with an opinion that there was no way of reaching the perpetrators of this act under the United States statute. It was in view of this that the bill was drawn up by the Commissioner of Public Lands and endorsed by the Secretary of the Interior, for without such legislation it would seem that fires may be kindled deliberately to the destruction of any quantity of Government timber, not to speak of the destruction of human life which often happens in such cases, while the Government is powerless to punish any one for this crime, and that, too, in spite of the fact that in response to an appeal from the Governor of this very territory of Idaho, the United States Government had expended a large amount of money in fighting these forest-fires, in order to protect its citizens from personal loss.

And now when this bill, which seems so fair and just, was before the Senate, Mr. Teller, of Colorado, objected to it (and the bill was laid over in accordance with this objection) on the ground that the Government of the United States cannot create any offense in the state of Colorado or in any other state except on those lands where they have exclusive jurisdiction. That is, the United States Government has no authority to say what shall be larceny or what shall be a misdemeanor on the public lands in the state of Colorado. It has no right to make it a criminal offense to burn timber in the state of Colorado, for the relation of the Government to its timber in that state and to its land is the same as that of any other proprietor. Now if Senator Teller's position is correct—that is, if the United States Government has no power to legislate against offenses committed in the states against its property—it is pretty clear that some comprehensive forest-policy should be inaugurated so that the Government property can be guarded by a sufficient number of watchmen. If the United States has no power to punish incendiaries who burn over its timberland, it would seem to be folly to wait longer before some thoroughly organized administration of the forest-lands, with state co-operation if necessary, is attempted. It does seem, however, that the United States ought to be able to devise methods for protecting its own property even among the God-fearing and law-abiding freemen who inhabit our western states.

The Silk Cotton-Tree.

THE traveler from the north, landing at Nassau, the principal town in the Bahama group of islands, will, if it happens to be his first introduction to the tropics, be most delighted certainly with the beauty of the Cocoanut Palms, with their tall, straight stems crowned with the great tufts of graceful leaves which sway backward and forward with the slightest play of the wind. But next to the Palms, the great tree, of which a portrait is published on page 347, will, if he has any interest at all in the products of Nature, excite his astonishment and curiosity more than anything else on these islands. It is a fine specimen of the Silk Cotton-tree of the West Indies, which botanists call *Eriodendron anfractuosum*. The generic name is formed from two Greek words meaning wool and tree, and was given to it on account of the brown woolly substance which surrounds the seeds, while the specific name, which means the bending in and out of a road or path, was bestowed upon the tree on account of its great size, which made it easier to divert a road round the trunk than to cut down the tree.

The specimen whose portrait we publish stands just in front of the town-house of Nassau, where it was planted probably in the early days of the settlement of the island, as the branches have attained a spread of 150 feet, while a man walking round the buttresses which support the trunk, and which are well shown in our illustration, must make fifty paces.

The Silk Cotton-tree is the largest inhabitant of the Caribbean forests. Few trees have a loftier and more imposing appearance; as it overtops its companions in the forest, or appears in solitary grandeur on some open plain or by some cultivated field, with its stout trunk strengthened in old age with numerous buttresses, and dividing sometimes near the ground into enormous spreading branches, and sometimes shooting up into a great column sixty or eighty feet high. The branches and the trunk of young plants are armed with straight acuminate spines. The ample glabrous leaves are palmately divided into six or seven oblong-lanceolate leaflets. The flowers, with their persistent calyx and five reflexed pale rose-colored petals, joined with each other, and with the three-branched column formed by the united filaments, are produced in the greatest profusion, and possess the delicate fragrance of primroses. The fruit is a large, woody, round, obtuse capsule, consisting of five cells, and splitting open by five valves, each cell containing a number of

broad seeds surrounded by dark brown cotton similar in character to that of the Cotton-plant, which botanically is nearly related to this tree.

The Silk Cotton-tree grows very rapidly, and the branches, like those of the Gumbo Limbo, another West Indian tree, which is common also on the islands of south Florida, have the power when cut and set in the ground of developing roots and growing rapidly into large trees. This makes it an easy plant to propagate, and it is frequently planted as a shade or road-side tree, not only in the West Indies, but in all other tropical parts of the world. The great size of the trunks, their lightness, and the ease with which the wood can be cut, enabled the Caribs to make from the Ceiba, as they called this tree, their great war canoes, in which they traveled safely over wide distances of open sea. The young leaves are mucilaginous, and are sometimes used by negroes as a substitute for the okra, which is the fruit of another plant of the same alliance; and the cotton which surrounds the seeds, although the fibre does not permit of its being woven into cloth, is sometimes used in stuffing furniture.

The imposing size and great beauty of this tree, and possibly the belief that the woolly appendage of the seed might prove of greater value than it has turned out to be, attracted the attention and excited the wonder of travelers in the early days of the discovery of the new world. Oviedo y Valdes, who landed in San Domingo in 1514 and wrote the earliest account of the natural history of America, was the first author to mention it, and from Oviedo's day to the present the Silk Cotton-tree has been described more or less in detail by every author who has written of the natural features and productions of the West Indies and the Spanish main.

Eriodendron belongs to the tribe of the *Bombaceæ* of the Mallow family, of which several other remarkable plants are members. It contains some of the largest trees. The African Baobab, the *Adansonia* of botanists, its near ally, is one of the marvels of the vegetable kingdom. The trunk of this tree sometimes attains a circumference of a hundred feet, and individuals were estimated once to have lived through six centuries. Later investigations, however, do not sustain such theories, as the Baobab is now known to grow like the other trees of its family with great rapidity. It is a native of the Cape de Verd Islands and other parts of west tropical Africa, where the negroes regard it with superstitious veneration, rendering it sacred by attaching bracelets to the trunk and branches in the hope of securing it from injury at the hands of the profane. The thin bark, which covers trunk and branches, is green, and appears to perform, to a certain extent, the functions of leaves, which only remain on the branches during three or four months of the year. It is the pulp that surrounds the seeds of this tree which is believed to have furnished the *Terra lemnia*, the mysterious powder brought to Egypt by the caravans and held in high repute by the physicians of the ancients for the treatment of many diseases. Another species of *Adansonia* inhabits Madagascar, and a third is Australian.

To the *Bombaceæ*, too, belongs the Durio (*Durio zibethinus*), a large tree of the Indian Archipelago which furnished the Durien fruit, one of the most delicate and esteemed of all tropical fruits, although it possesses an odor which is unspeakably offensive to people when they first smell it, but which is unnoticed when once the taste for it is fairly acquired. This fruit forms a large part of the food of the native population in some regions of the East Indies, and as the trees are always left standing when the forests are cleared off for cultivation, the Durio is one of the conspicuous features in many eastern tropical landscapes. It is cultivated all over the east for the fruit, while the wood, like that of another plant of the same relationship, the Asiatic Bombax, has many useful qualities.

We are indebted to Mr. William B. Bacon, of Boston, for the photograph of the great Silk Cotton-tree at Nassau, from which our illustration has been made.

The Economic Uses of Leaves.

EVERY part of plants and trees is more or less utilized by savage and civilized men—the roots, stems, sap, bark, fruit and seeds, and leaves. If we take the foliage, apparently the most insignificant part of the plant, how dependent are we on these for food, clothing, medicine, dyes, stains and various comforts. In tropical countries especially the domestic uses of leaves are almost innumerable.

The leaves of many Palms are largely employed for making hats. Those best known are Panama hats, made from the finely-plaited fibre of the leaves of a South American Screw Pine (*Carludovica palmata*). The tree occurs only on the slopes of the Andes. About 200,000 dozens of these hats are made in Ecuador and different states of South America, and they are distinguished from all others by consisting only of a single piece and by their lightness and flexibility; they may be rolled up and put in the pocket without injury. The plaiting of the hats is very tedious and troublesome; the coarse ones may be finished in two or three days, but the fine ones take as many months to plait. They vary in price, according to fineness and quality, from five dollars to a hundred dollars. The unexpanded fronds of *Livistonia australis*, prepared by being immersed in boiling water, are dried, and the fibre thus obtained is much valued for the manufacture of hats in Australia which much resemble the celebrated Panama hats.

The rough leaves of the Chumico (*Curatella Americana*) and of *Davilla lucida* are used for cleaning iron and polishing and scouring wood. *Curatella alata* is used in the West Indies for polishing bows, sabres, etc.; and in Brazil *C. sambaiba* serves all the purposes of sand-paper to the Indians for polishing their blow-pipes and war clubs. The leaves of *Celtis orientalis* are used for polishing horns in the East Indies.

The foliage of *Guaiacum officinale* is very deterrent, and is frequently used in the West Indies to scour and whiten floors, which it is said to do better than soap.

Leaves sewn together are much used in India as substitutes for the plates and dishes of more civilized life. It is not always poverty that leads natives to use them in preference to metal or porcelain articles, as caste or custom has often some influence in the matter. The leaves principally used are those of the Egyptian Lotus; those of the Banyan by Brahmins, and the Plantain-leaf.

The leaves of *Bauhinia Vahlia* are used in the construction of the curious, rude leaf-bellows in Sikkim, with which the natives of the hills smelt iron. These leaves, when sown together, are used as plates, cups, rough table cloths, rain-hats and caps. The leaves are heart-shaped and above a foot in breadth, and the same in length. Sewn together with twigs, they also serve for baskets for holding pepper, turmeric and ginger, and are likewise used for thatching.

Under the name of "Chattahs," a kind of umbrella-hat or sun-shade is made in the East of the leaves of the *Licuala peltata* and the Talipot Palm. These Chattah hats are much worn by the plowmen and coolies of Bengal and Assam.

The large fan-shaped leaves of the Talipot Palm are like those of the Palmyra Palm, carried over the heads of people of rank as an umbrella, and are also used for making books and for various domestic purposes. They are also cut up into neat bracelets, worn by Santal girls in India. Those of *Vanda Roxburghii*, split, are also worn by them as anklets. Those of another species, *Borassus Ethiopicus*, occur as much as twelve feet across, and serve also for the manufacture of baskets, mats, ropes and sieves. The leaves of *Nipa fruticans* attain a height of fifteen to twenty feet, presenting a very handsome appearance, resembling the fronds of huge Ferns. This graceful eastern Palm is utilized in various ways, the principal being in the manufacture of thatching for house-roofs. This manufacture is quite an industry of itself, and affords employment to many natives, chiefly women, the men simply bringing cargoes of the fronds to the women, to be stitched with split rattans, and made up. Atap roofs are the best adapted for these climates, for while the winds are never strong enough to blow them away, they afford the coolest protection against the sun of any kind of roofing known.

The leaves of the Palmyra Palm were formerly used like paper, to write books on, and to this day they are applied to this purpose in Orissa, southern India, and Ceylon, where an iron style is employed to write upon them; in Bengal young children use them to write the alphabet lessons on. They are largely employed for making pans, bags, winnows, hats, umbrellas, and for thatching, etc. The leaf takes a dye well and is worked up in Madras into pretty colored patterns in baskets and mats.

The slips of Talipot and other Palm leaves are coming into European commerce for the manufacture of ornamental

braids, and in the construction of straw or Leghorn hats. The fibre obtained from the base of the leaves of the Chusan Palm is used by the Chinese for making hats and coarse clothing. The sale of Palm leaves for decorative purposes in the towns of Elche and Alicante, in Spain, produces a considerable income to the towns.

Kadjan mats, manufactured out of Nipa leaves, are indispensable for traveling purposes; packed up in the smallest compass when not required, each mat is capable of affording sufficient cover at night for two or three persons, either in boat or forest-journeys. They also form, almost exclusively, the material for side-walls and divisions in houses. The young leaf unfolded and dried, under the name of Roko, forms the favorite covering for cigarettes in the Malayan Peninsula in preference to paper.

The large leaves of the Teak-tree are used for plates, for packing, and for thatching. The leaves of *Cordia myxa* are employed as plates in Pegu, and to cover Burmese cheroots. In Bangalore the leaves of *Canna Indica* are used by the natives in lieu of plates, to serve their Millet puddings and other dishes on.

The leaves of the Papaw-tree are employed by the negroes in washing linen, as a substitute for soap. They have also the property of rendering meat wrapped in them tender, owing to the alkaloid papain which they contain, and which acts as a solvent.

For cordage and other textile purposes, numberless leaves are used, and they serve very generally for packing and wrapping up small parcels in India.

In Guiana, Tibusiri fibre is obtained from the inner surface of the spiral leaves of the Ita Palm (*Mauritia flexuosa*); it is used by the Indians for making hammocks, etc. The leaves are cut before they are open, and the midrib separated by drawing each division of the leaf through the finger and thumb. After drying, the fibre is ready for use without further preparation. About a quarter of a pound may be procured from each leaf, and if the central leaf is left uninjured, no evil effect is produced on the tree. Bags or matting could be cheaply and easily made from this fibre, as well as hats similar to those known as Panama.—*Gardeners' Monthly*.

Cooking Quamash.

WHILE camped at Deer Park, on the Lower Arrow Lake (an expansion of the Columbia River), a week since, I had an opportunity of witnessing the Indian mode of cooking *Camassia esculenta*. This species of *Camassia* is very abundant along the Columbia River, between the Upper and Lower Arrow Lakes, flowering there during the first weeks of May. The bulbs were collected by the Indians before the seed was fully matured, at which time they consider them at their best. The party I speak of had between twenty and twenty-five bushels of them at the lowest estimate. For two or three days before cooking was begun, the women of the party were engaged in cutting and carrying to camp branches of the Alder and Maple (*Alnus rubra* and *Acer glabrum*). Several bundles of the broad leaves of *Lysichiton Kamtschaticense* (Skunk-cabbage), and two or three of *Alectoria jubata*, the black hair-like lichen that grows in profusion on *Larix occidentalis*, had been brought with them.

Everything being ready, the men of the party cut down a huge Pine for no other object, apparently, than to obtain its smaller branches, as no other portion of it was used. A hole about ten feet square and two deep was then dug in a gravelly bank near the lake-shore, which was filled with broken Pine branches. Upon these were piled several cords of dry cedar and pine, and this was covered over with small bowlders. The pile was then lighted in several places, and left for some hours to take care of itself. When the Indians returned to it the stones lay glowing among a mass of embers. The few unburnt pieces of wood which remained near the edges were raked away, and the women with wooden spades banked up the sides of the pile with sand, throwing enough of it over the stones to fill up every little crevice through which a tongue of flame might be thrust up from the coals that still burned beneath the stones. Then the whole was covered with the Maple and Alder boughs to the depth of a foot or more after they had been well tramped down. Over these were placed the wide leaves of the Skunk-cabbage until every cranny was closed. Sheets of Tamarac-bark were then spread over the steaming green mass, and upon these the bulbs were placed. About half of them were in bark baskets closed at the mouth, and each holding about a bushel and a half. These were carried to the centre of the pile. The lichen of which I have spoken was then laid over the unoccupied bark, having been

well washed first, and over it were strewn the bulbs that remained. The whole was then covered with boughs and leaves as before and roofed with sheets of bark. Upon this three or four inches of sand was thrown, and over all was heaped the material for another fire, larger even than the first one. When this was lighted the sun was just setting, and it continued to burn all night.

The next morning our camp was moved away, and I was unable to see the results of the day's labor. I was told, however, by one of the Indians who could speak a little English, that their oven would be allowed a day in which to cool, and that when opened the bulbs in the baskets would have "dissolved to flour," from which bread could be made, while those mixed with the lichen would have united with it to form a solid substance resembling black plug tobacco in color and consistency, which could be broken up and kept sweet for a long time.

Sproat, E. C.

James M. Macoun.

An Experience with Rosebugs.

THE Rosebug, or, more correctly, Rose-chaffer, was known as a difficult subject to Harris and Fitch and the entomologists of their day. They gave us a fair life history of the insect, to which Dr. Riley has quite recently added a good description of the larva, with figures, as well as some further biological notes. Each of these authors seems to have been fully aware of the difficulty of dealing with the insect, and the recommendations as to remedies are vague and unsatisfactory. Fitch gives an excellent description of the way in which the invading swarms cover everything, apples and other fruits becoming so covered that a mere mass of yellow sprawling beetles indicates that here probably is a fruit!

Southern New Jersey has been invaded for several years past by swarms of this pest, which cleared out the grape crops so completely year after year, that many vineyards have been taken out and others will be abandoned unless some practical remedy is found. With the view of testing the value of the published methods I spent some days in the invaded districts. I found that, as a rule, the insects did not breed in cultivated land, but that on the other hand the entire sand region is a vast breeding ground, pupæ being found even at the very sea-shore. From these breeding places the insects emerge and fly about, searching for food, the winds apparently influencing their direction to some extent. Vineyards are therefore generally invaded from the edges, newly arriving hordes ever advancing further. They are not at all dainty in food habits, but do show some preferences. Sumach is readily eaten; Apples and Cherries are tidbits; Sour Gum attracts them by the million; Hollyhocks are eaten, stems and all; Roses are high favorites, while the Peach is not so much liked. In fact, there is scarcely a plant they will not eat, though flowers and some fruits are always preferred. A field of Blackberries at Colonel Pearson's place was swarming with them, and the Colonel told me that last year his Strawberry patch looked yellow where red ought to have been seen.

Pyrethrum has been highly recommended for these insects. I tried it first at the rate of one ounce to one gallon of water. It acted in about ten minutes, the majority of beetles tumbling from the Blackberry-bushes to the ground. Only a few, however, were really stupefied, and most of them began crawling back upon the plants immediately, where, as soon as the sun dried them, they fed as freely as before. Then I increased the dose to one-fourth of a pound to a gallon of water. The effect was more prompt, the resulting stupor more lasting, but half an hour later all were again feeding on blossoms that were yellow with pyrethrum! The insects will live for an hour or two in the pure powder, and recover when removed from it. Tobacco seems to give an added relish to the plants upon which it is applied. Sprayed on at the rate of a pound to the gallon, the powder being added to the decoction, the beetles never stopped eating. London Purple applied as strong as the grape would bear did not prevent the destruction of the blossoms, but left a sprinkling of dead beetles on the ground. Powdered naphthaline, pure, and mixed with carbonate of lime, was dusted over a row of vines with the most approved appliance, so as to leave the vines white. This had not the slightest effect, so far as the blossoms are concerned, and the leaves were eaten from below instead of from above. Carbonated lime was equally ineffective, as was also the pure hydrate of lime, which is better than air-slaked lime, as a rule. Hellebore applied pure is utterly ineffective. Mrs. Treat showed me some Foxgloves in her garden, each plant surrounded by dead Rosebugs. Colonel Pearson thereupon made an infusion of leaves, which was ineffective, while I fed a lot of the beetles for a week upon Roses which were

soaked in a saturated solution of digitaline! Quassia is useless, and so were all the copper compounds, the saturated solution of lime, the iron solutions, the kerosene emulsion; and, in fact, everything else that was applied. All this goes to show what a tough subject we have to deal with. Corrosive sublimate will kill him readily, but, unfortunately, kills the plants as well. A sludge-oil soap, obtained too late to test thoroughly, kills the beetles without injuring plants. It is probable that in this we have a good remedy for the *Macro-dactylus* if it can be made cheaply enough.

Of the mechanical means tried, an umbrella with a sack attached into which the beetles were jarred proved satisfactory, and this can be used at all times of the day, since the beetles cannot fly out of a sack as they could off a sheet or from the ground.

My conclusions are that the only way to save a crop of grapes is to plant *Spiræa*, *Roses* or *Blackberries* between some rows of the vineyard and by persistent collecting keep these plants free and attractive. How persistent one must be is shown by the fact that though Colonel Pearson one year went over his vineyard once a day killing beetles, yet they destroyed his grapes almost completely. This year, though, he daily cleared his *Rose* bushes by applying the sludge-oil soap, yet every bud was eaten.

The *Clintons* many of them bloom and set before the *Rose-bug* arrives in force; they are then generally safe, since the beetles prefer the foliage to the grape. The *Concord* buds are just right for the insects and they go completely. The *Concord* foliage is not relished and only the upper surface is eaten. Very late blooming varieties are also fairly safe, and this indicates another method of dealing with this pest—i. e., plant very early or very late blooming varieties while supplying something for the insects to eat. I may say that the suggestion that *Spiræa* be planted as an attraction is Mr. Fuller's, and that he reports that he saves his grapes in this way.

There is one glimmer of hope ahead! Indications of a decrease in the number of the insects are observed, and natural means may end the invasion. Some eighteen or twenty years ago there was a similar invasion, lasting four or five years. The present flood began about four years ago, and in some places is undoubtedly on the decrease. Colonel Pearson did not suffer nearly as much this season as he did last season, and others have made the same statement.

Rutgers College.

John B. Smith.

Notes on North American Trees.—XIX.

Description of the Wood of Certain Species.

Acacia Farnesiana. Wood very hard and heavy, close-grained, containing many evenly distributed open ducts; layers of annual growth hardly distinguishable; medullary rays thin, numerous, conspicuous; color rich reddish brown; specific gravity, 0.8220, 0.8387, average 0.8304; ash, 1.15, 1.18, average 1.17; weight per cubic foot, 51.74 pounds; fuel value, 0.8207. Collected by C. G. Pringle in the valley of the lower Rio Grande.

Acacia flexicaulis. Wood exceedingly heavy and hard, compact, close-grained, satiny, containing many minute evenly distributed open ducts; layers of annual growth hardly distinguishable; color very dark rich reddish brown slightly tinged with purple, the sap-wood clear bright yellow; specific gravity, 1.0482, 1.0289, average 1.0386; ash, 3.30, 3.27, average 3.28; weight per cubic foot, 64.72 pounds; fuel value, 1.0046; unsurpassed in value as fuel by the wood of any tree of the lower Rio Grande valley, and used for pulleys, rollers and other objects demanding great strength and solidity. Collected by C. G. Pringle in the valley of the lower Rio Grande.

Prunus ilicifolia, var. *occidentalis*. Wood heavy, hard, very close-grained, satiny; layers of annual growth plainly marked; medullary rays thin, conspicuous; color pale reddish brown, the sap and heart-wood hardly distinguishable; specific gravity, 0.8340, 0.7654, average 0.7997; ash, 0.84, 0.95, average 0.90; weight per cubic foot, 49.84 pounds; fuel value, 0.7927. Collected by T. S. Brandegee on Santa Cruz Island, California.

Crategeus Crus-galli, var. *berberifolia*. Wood heavy, hard, very close-grained, satiny, susceptible of a good polish; layers of annual growth hardly distinguishable; medullary rays numerous, very obscure; color brown tinged with red,

that of the sap-wood rather lighter; specific gravity, 0.6111, 0.6141, average 0.6126; ash, 1.52, 1.71, average 1.62; weight per cubic foot, 38.17 pounds; fuel value, 0.6027. Collected by C. E. Faxon and C. S. Sargent near Opelusas, Louisiana.

The wood of the variety is considerably lighter than that of the species, as determined by the Census investigations (average 0.7194).

Lyonothamnus asplenifolius. Wood very heavy, hard, close-grained, compact, satiny, susceptible of a good polish; layers of annual growth hardly distinguishable; medullary rays numerous, thin, obscure; color bright clear red faintly tinged with orange; specific gravity, 0.8358, 0.7700, average 0.8029; ash, 0.53, 0.49, average 0.51; weight per cubic foot, 50.05 pounds; fuel value, 0.7988. Collected by T. S. Brandegee on Santa Cruz Island, California.

C. S. Sargent.

New or Little Known Plants.

Ilex longipes.

THE species of *Ilex* fall into several natural groups which are readily separable when the necessary characters are at hand, but it is hard to satisfactorily discriminate between certain of the component species of these groups. The plant that Mr. Faxon illustrates in this number is one of these (p. 345). Drummond, Beaumont and Buckley collected it many years ago in the south, and their specimens mainly appear in herbaria as *I. decidua*, of which species Dr. Gray held it to be a variety. Some years since it was found in Tennessee by Dr. A. Gattinger, who referred it to *Nemopanthes Canadensis* in his list of Tennessee plants, but, on sending it to Dr. Chapman, received the above manuscript name for it.

In its general characters *Ilex longipes** is quite similar to *I. decidua*, but differs in its elliptical or broadly lanceolate leaves, sparingly ciliate, with short, broad hairs, but otherwise glabrous, whereas those of the latter are broadest toward the apex, so as to be spatulate or oblanceolate, and apparently always pubescent on the under side, at least on the midrib. The most striking difference, however, and that to which the species owes its name, is in the fruiting pedicels, which, in this species, are about an inch long, whereas in *I. decidua* they scarcely exceed the drupes in length.

So far as is shown by herbarium specimens, *Ilex longipes* occurs from North Carolina and Tennessee southward to Alabama and Louisiana. It is not yet known in cultivation.

Shaw School of Botany, St. Louis.

W. Trelease.

New Orchids.

IN complying with a request to furnish occasional reviews of new Orchids my purpose will be to give a summary of the novelties described in European horticultural publications. Many of the plants described have little value from a horticultural point of view, but it may be best to include most of the novelties and leave to cultivators the choice of kinds suited to their various tastes and requirements. A few Orchids not new may be sufficiently rare or interesting to deserve notice.

ERIDES AUGUSTIANUM, Rolfe, is one of the earliest novelties described in the present year. It was discovered in the Philippines by M. Auguste Linden, after whom it is named. It is allied to *A. Rabelenii*, Rchb. f., but the flowers are of a light, rosy tint instead of yellowish white. It is described in the *Gardeners' Chronicle* on January 4th, p. 9, and also figured in that journal on February 22d, p. 233, fig. 36, and in *Lindenia*, vol. 5, p. 39, t. 210.

CYPRIPIEDUM × *NIOBE*, Rolfe, is a very elegant hybrid raised from *C. Spicerianum* fertilized with the pollen of *C. Fairieanum*. It was raised by Mr. Seden for Messrs. James Veitch & Sons, of Chelsea, and was awarded a first-class certificate by the Royal Horticultural Society, December 11th, 1889.—*Gardeners' Chronicle*, January 4th, p. 9.

ANGRÆCUM ICHNEUMONEUM, Lindl., is a curious little plant which has long been known to science, but which has been

* *Ilex longipes*, Chapman, ined.—Trelease, in *Trans. St. Louis Acad. Sci.*, v. (1889), 346.

somewhat recently introduced to cultivation. The flowers reminded Dr. Lindley of an ichneumon fly, hence the name. The curiously inflated spur is much like the bladder of a small fish. The white flowers are borne in long, pendulous racemes, yet the plant is rather curious than beautiful.—*Gardeners' Chronicle*, January 11th, p. 38.

CYPRIPEDIUM \times CYTHERA, Rolfe, is a pretty little hybrid, raised in the collection of Mr. R. H. Measures, of Streatham. It is said to be derived from *C. Spicerianum* fertilized with the pollen of *C. purpuratum*. The flowers much resemble the former, and curiously enough there is no trace of tessellations in the leaves, yet the dwarf habit and some characters in the

C. \times Lathamianum, a fact overlooked at the time the other was described.—*Gardeners' Chronicle*, January 25th, p. 105.

CALANTHE \times VEITCHII ALBA, Rolfe, is a very beautiful hybrid raised in the collection of Sir Charles Strickland from *C. vestita* and *C. Rosea*; thus it has either the same or the inverted parentage of *C. \times Veitchii*. It is, however, markedly different, having the strongly four-lobed lip of *C. vestita*, while the flower is of the purest white, without any trace of color anywhere. It is a great horticultural acquisition.—*Gardeners' Chronicle*, February 1st, p. 132.

PHALÆNOPSIS \times CYNTHIA, Rolfe, is a handsome natural hybrid between *P. Aphrodite* and *P. Schilleriana*, which appeared

Fig. 46.—*Ilex longipes*.—See page 344.

flower appear to be derived from the other parent.—*Gardeners' Chronicle*, January 18th, p. 73.

DENDROBIUM \times XANTHOCENTRUM, D. \times JUNO and D. \times LUNA, are three hybrids raised in the collection of Sir Trevor Lawrence, which received first-class certificates at a meeting of the Royal Horticultural Society on January 14th last. The first, which resembles *C. \times Schneiderianum*, was obtained from *D. Findlayanum* and some unknown species, the second from *D. Wardianum* and *D. Linawianum*, and the third from *D. Findlayanum* and *D. \times Ainsworthii*.—*Gardeners' Chronicle*, January 18th, pp. 87, 88.

CYPRIPEDIUM \times HERA, Rolfe, was raised in the collection of Mr. R. H. Measures, of Streatham, from *C. villosum*, crossed with the pollen of *C. Spicerianum*. Thus it is identical with

in the collection of Mr. F. Wigan, of East Sheen. It approaches the last named species in most of its characters, the front lobe of the lip being almost identical in character, while in *P. \times leuconrhoda* and *P. \times casta*, which have the same parentage, that organ is long and slender, as in the other parent. A paler variety with the same structure has since appeared with Messrs. Hugh Low & Co.—*Gardeners' Chronicle*, February 1st, p. 132; February 22d, p. 227.

CYPRIPEDIUM \times NORTHUMBRIAN, N. E. Br., is a hybrid raised in the collection of Mr. D. O. Drewett, between *C. \times calophyllum* (itself a hybrid between *C. barbatum* and *C. venustum*), and *C. insigne Maulei*, the latter being the pollen parent.—*Gardeners' Chronicle*, February 8th, p. 160.

CYPRIPEDIUM SIAMENSE, Rolfe, is a species introduced by M.

J. Garden, of Paris, from the neighborhood of Bangkok, in Siam. It is allied to *C. callosum*, and a colored figure which appeared in the *Moniteur d'Horticulture* for March 10th suggests the question whether it is botanically distinct from that species. —*Gardeners' Chronicle*, February 8th, p. 161.

Kew.

R. A. Rolfe.

Cultural Department.

Notes on Shrubs.

SHRUBS which have the habit of blooming in the early part of July are not numerous in species in this latitude and every one which makes any show is valuable even if it has defects which would cause an earlier flowered species to be considered of little value. There appears to be a slight cessation of blooming among the shrubs just now, but a little later a series of late flowering species becomes quite conspicuous.

Itea Virginica, for which no more popular name than its generic one appears to have been invented, is a rarely cultivated shrub which is especially valuable for blooming at this season, and it usually attains its best condition in the first week of July. It is a dwarf shrub of slender habit and under cultivation it seems to rarely grow to a height of more than two or three feet. The flowers are borne in dense, terminal, almost perfectly cylindrical racemes from two or three to four or five inches in length, and about or nearly three-fourths of an inch in diameter. Although the pointed, narrow petals are white or creamy white, a greenish white effect is given to the racemes by the stamens and pistils, and the outside of the flowers, which are light green in color. The fragrance seems to have something of the qualities of the wild Grape and of *Clethra* blossoms, but is not so strong or sweet as either. The rich color assumed by the foliage in autumn is another quality which makes these plants desirable for the shrubbery. Although a native from New Jersey southward, the *Itea* is perfectly hardy in Massachusetts. Where naturally-grown plants cannot be obtained and transplanted from their native habitat they may be propagated in the usual way by seed, by cuttings, or by division of the roots, which slowly spread and form clumps of stems.

Probably the most conspicuous flowering hardy shrub at this season is our common Elder (*Sambucus Canadensis*), which blossoms here in the last of June and first week or two of July just as the flowers of one of the latest *Viburnums* (*V. molle*) are fading. The common Elder is usually considered valuable on account of its general freedom from disease. But there are complaints this season from various parts of the state of serious destruction caused by the Elder Rust (*Aecidium Sambuci*), both to plants cultivated for ornament and those growing wild. This fungus attacks both the leaves and young shoots, and its effect is to cause large swellings and distortions of the parts diseased. When the spores are ripe the swellings have a dusty yellowish appearance. So serious has this disease appeared in some localities this season that it seems as if the destruction of the Elders must inevitably follow. No remedy can be at present suggested except to cut off and at once burn the affected portions before the spores reach maturity. The Elder Rust is found over a large extent of the country, probably wherever the Elder is indigenous.

Notwithstanding the many beautiful hybrids and other forms of *Rhododendrons* which have been produced by the skill of the hybridist or horticulturist, there are few which possess a greater charm and delicacy of color than our native *R. maximum*. Its value is enhanced in the eyes of all admirers of beautiful flowers by its habit of blooming in July when it has no conspicuous competitors, the blossoms of nearly all other *Rhododendrons* having long since faded. But besides this evergreen *Rhododendron* we have two other native deciduous species, belonging to the *Azalea* section of the genus, which bloom at about the same time. These are our common Clammy *Azalea* or so-called White Swamp-Honeysuckle (*R. viscosum*), and the Smooth *Azalea* (*R. arborescens*), which is not found so far north. The flowers of the Clammy *Azalea* are comparatively so small that they are not so valuable for ornament as they are for the fragrance which they exhale. The plant grows freely and flowers profusely in cultivation, becoming a tall, upright-growing shrub.

But the Smooth *Azalea*, figured on page 401 of the first volume of GARDEN AND FOREST, is greatly superior to *R. viscosum*, inasmuch as its flowers combine fully as rich a fragrance, with more than double the size, and, besides, are much less clammy. Although the flowers are partly hidden by the foliage, they are not more so than is necessary for protection from the withering influence of the hot summer sun. The corollas expand in their widest part fully two inches

across from tip to tip of petals. They are usually white, but vary in some plants toward a decided rosy tinge of color. The long stamens and pistils are bright red, becoming paler or light pink toward the base, and the anthers are yellowish. In this climate the blossoms are usually in their best condition during the last week of June and first week of July, and may be counted but very few days in advance of those of *R. viscosum*. Plants of *R. arborescens*, raised from seed collected in North Carolina, and now ten years old, are bushes from three to four feet high, with as great a spread of branches. They are perfectly hardy, but, as a rule, not very profuse in their bloom. In its native habitat it is said to become fifteen or twenty feet in height, but its low spreading habit in open cultivation here is in striking contrast with the more erect habit of plants of *R. viscosum* of the same age. *R. arborescens* does not appear to have been much used in hybridizing with other species.

Arnold Arboretum.

J. G. F.

The Strawberry Season.

THE Strawberry season of 1890 was a short one. On June 3d I picked the first ripe berries of Pearl, Jessie and Bubach. I could probably have done this on the 1st had not my friends, the birds, been sampling them since they began to color. The Bubach had probably been overlooked, which accounts for my ability to pick it with the others, as it is generally two or three days later. On the 5th I was able to pick three quarts for the table and the season was fairly open.

I find on reference to my notes of last season that this was three days later than last year, and the last picking of any amount was made on the 21st, though there were a few late comers until the 26th.

The quality of the fruit was good as long as sunny weather prevailed. On the 12th, 13th and 14th rain fell freely, and the three following days were dull, so the abundance of moisture and the absence of sunshine soon caused a depreciation in flavor, and bad color. The berries at once became soft and decayed quickly, and the blight was on hand to do its fatal work. This reduced the crop very materially and necessitated great care in picking.

The Pearl still suits me for size, shape, beauty, vigor and quality. It ripens evenly and the berries from the largest to the smallest are generally perfect in shape and well filled out.

The Jessie occasionally produces a large berry of cocks-combed shape, but on the average the fruit runs no larger and yields less abundantly on my soil. The chief fault of the Jessie with me is its uneven ripening. For the first week, at least, one third or more of the berries which were crimson on one side were white or green on the other. This adds very much to the time and labor of picking if one is careful to avoid picking the unripe ones. Toward the close of the season this feature is less apparent. Mr. Charles A. Green, the introducer of this berry, tells me that this characteristic does not develop at Rochester.

The Bubach, as a rule, is a little later than Jessie. It is a vigorous grower and productive. The first berries to ripen are generally twins, but perfect in shape. The texture and quality is not quite as good as the preceding, and the rain and absence of sunshine told on them in this respect more severely. For productiveness and large size under favorable conditions this variety will give great satisfaction even though the quality is a little inferior to that of others.

Jewell is very much like it in texture and quality and more subject to rust, so much so as to render it quite worthless with me, and each successive season it seems to be more subject to these fungi. If this proves to be the case with Bubach it will be short-lived. Last season I did not notice that it was at all affected, and I had higher hopes of its future than I have now. Belmont produces a few large berries at first, but like the Sharpless the later settings are abnormally developed and unsightly. A poor cropper it is, too, with me.

I have many newer varieties, but a single season's experience will not justify any judgment of their merits.

Montclair, N. J.

E. Williams.

Among the more recently introduced Strawberries none are proving more generally satisfactory in our state than the Warfield No. 2, Jessie and Haverland. The peculiar merits of the Warfield lie in its deep, brilliant and glossy color, which gives it a most attractive appearance, the firmness of its flesh and skin, which enables it to endure carriage remarkably well, and its great productiveness, which renders it a very profitable variety to grow.

The Jessie surpasses the Warfield in size and quality, and possesses the further advantage of being perfect in flower.

At the recent summer meeting of the Wisconsin State Horticultural Society, the Warfield and Jessie were pronounced the most profitable market varieties, the Jessie being used as a fertilizer for the Warfield. The superior quality and large size of the Jessie render it a favorite garden variety wherever it has been introduced, while in productiveness it is little inferior to the Warfield, or any other variety thus far tested.

The strong point of the Haverland lies in its great productiveness. Aside from this it would hardly attract attention. Bubach No. 5, though very fine as a berry, does not appear to possess the vigor and prolificacy of the above named sorts. The Cloud does not promise well. I have not yet seen a favorable report from it in Wisconsin. Gandy is proving fairly productive of large and good looking fruit. Gypsy is very promising as a first early sort. It ripened with the earliest bearing of the Crescent, and while not equal to the latter

from a nursery company. These were given similar care, but the plants from the nursery have been already nearly destroyed by the rust, while those received from Mr. Smith are almost free from it.

University of Wisconsin, Madison, Wis.

E. S. Goff.

Our Strawberry crop is now just past its best (June 30th); but for the excessive heat of the past week we should have had most excellent picking till after the 4th of July. I think it an underestimate to put the loss from sun-scald at twenty-five per cent., besides the softening of as many more, which we could only save by shipping them to a near market; still, in spite of the excessive rainfall and this continued heat, the crop, even at from five to eight cents a quart, has paid better than any of its predecessors for ten years.

The Silk Cotton-Tree at Nassau.—See page 341.

in productiveness, very far surpasses it in quality. Lady Rusk is thus far disappointing. It is only moderately productive, and the fruit is small, deformed and insipid. Welch promises well. The plant possesses remarkable vigor and is quite productive. The fruit is large and of good quality, but its pale color will hardly favor it as a market variety. Pineapple is of high quality and fairly productive, but like the above its pale color will not commend it for market.

In a few localities the Wilson still maintains popularity, but it is generally so much injured by rust as to be no longer profitable. Some reasons appear for believing that the liability of this old standard to the rust is due in a measure, at least, to an enfeebled condition of the plants. Mr. J. M. Smith, of Green Bay, has been remarkably successful with the Wilson, and has for years set out his new beds only from plants taken from thrifty young beds that have not yet borne a crop. In the spring of 1889 I procured some plants of the Wilson from Mr. Smith and about the same time some of the same variety

The six best-paying varieties are Jessie, Bubach No. 5, Warfield No. 2, Haverland, Crescent and Miner's Great Prolific. The Jessie is worthy first place here, because of its perfect blossom, large size, good quality and productiveness. After ten days' picking, without reserve, I stepped to the end of one matted row, two feet wide, and picked eight feet of the row for two quarts, and in each box there were a number of berries as large as hen's eggs; this was without selection. Haverland has suffered worse with the heat and sun-scald, and being soft and of poor quality, will not take high rank, though more productive and larger than Crescent.

We have potted Wilson, and still plant it for pollen, but unless the rows have at the rate of 100 loads of manure to the acre, it is not a paying berry; and among the fifty kinds we grow, of old varieties Miner's Great Prolific is ahead this season in size, productiveness and for pollen. For a late berry we find nothing superior to Gandy.

Janesville, Wis.

George J. Kellogg.

Notes on American Plants.

THE Maryland Pink Root (*Spigelia Marilandica*) is an attractive plant at the time of flowering, and its long red corolla is about as conspicuous as that of the Cardinal Flower. It is from six inches to a foot and a half high, bearing several tubular flowers over an inch long. The tubular or lower portion of the flower is about a third of an inch in diameter, tapering toward the base. The opening at the top is about half an inch wide and yellow inside. It is a herbaceous perennial, a native of rich woods from Pennsylvania to Wisconsin and southward. It likes a light, loamy soil in the shade.

Sedum pulchellum, a native of the southern states, is a pretty garden plant forming dense beds. Its stems are somewhat weak and often trailing, and are about eight inches long. At the summit is a several spiked cyme of pale rose-purple flowers. It is of little or no value for cutting, but is a pretty border plant, not only when in flower, but its dense foliage is handsome the season through. It needs a light soil and sunlight.

Calochortus Howellii, a newly discovered species from Oregon, has handsome white flowers an inch wide, with dark brown beards on the lower inner half. But the plant is not healthy in our light, loamy soil, and the leaves die before the flowers open. It might thrive in a heavier soil. We have known it but one season.

Pentstemon laevigatus, var. *digitalis*, is a desirable native species with larger and handsomer flowers than the more common *P. pubescens*. It is a native of rich, dry soils in the southern states. It grows two or more feet high, bearing numerous pale purple or white flowers an inch long. Though a native of a warmer climate, it seems perfectly hardy here and is certainly worthy of cultivation.

One of the easiest California Lilies to grow in this climate, and an attractive one, too, is the *Lilium pardalinum*. It seems to do well both in heavy and light soils, and unlike some of the species from the Pacific coast, the foliage shows much health and freshness during most of the summer. Its height here is about two feet, and it bears one to several (according to the strength of the bulb) good-sized, orange-red and spotted flowers, the divisions of which turn back to nearly meet the stems on which they are borne.

Another good species for light, loamy soils is *L. rubescens*, from the same state. This one, however, is more particular about its location, and in a clay loam it never seems to thrive with us. It is a valuable species bearing a dozen or more erect, nearly white, fragrant flowers with dark brown spots. With age the flowers turn to a reddish purple. They resemble those of the *L. Washingtonianum* in shape, size and color, but those of the latter are turned downward. This last species is not a healthy one in our light soil, and both flowers and leaves seem to die even before the flowers have opened.

Another interesting species from this state is the *L. Humboldtii*. It seems to need at least two years to become established. Then, if well fed, it will give a fine display of its large salmon-yellow and spotted flowers. We have found well decayed chip-dirt, sifted and applied as a top dressing, the best fertilizer for this species, and a soil having a slight mixture of clay seems to suit it.

Southwick, Mass.

F. H. Horsford.

Rose Notes.

A LARGE number of Roses have already been planted in preparation for next winter's cut-flower supply, some of the Hybrids for early forcing having been planted in the beginning of April, and in some progressive establishments the Teas followed shortly afterward.

Of course it requires some moral courage to clear out a Rose-house so early in the season, especially if the plants are in fair condition and still producing a respectable crop of flowers, but it undoubtedly gives the new planting a much better chance to become well established and to make some strong and vigorous growth before the days get too short. It is well to remember, however, that even though the Roses have been planted out in April or May it is not advisable to crop them too heavily in October, for the mid-winter crop may be correspondingly light if the plants are allowed to overtax their strength. Disbudding should therefore be regularly attended to until the flowers are needed in quantity. Strong, healthy young plants in three or four-inch pots are preferable for planting out, as the weak, stunted ones sometimes used as a makeshift for this purpose seldom start away properly, and as a consequence prove unsatisfactory for winter-blooming. It may be repeated that the Roses when planted out should always be moist at the root, for when the old ball of earth is dry at the time of planting it will be very difficult to moisten it afterward without making the soil in the bench or bed too wet.

As regards the two chief systems of planting Roses for winter flowering—that is, either the shallow bench system or the solid bed plan—it may be said that the first named is decidedly the most in favor, and it is now quite an exception to the rule to see a house planted on the solid or deep-bed system.

Neat staking and training adds much to the appearance of a Rose-house, and is certainly not detrimental to the plants, and this may easily be arranged by adopting the method used in commercial houses for several seasons, where the plants are supported by wires stretched from one end of the bench to the other. The wires are attached to a light post or other suitable support at each end of the bench, and the plants are tied to the wires as it becomes necessary. Stout galvanized wire is best for this purpose, as it does not rust out so quickly as the plain wire, and with proper care at the time of replanting it will last for three or four seasons. This makes a much more orderly arrangement than the old-fashioned method of individual staking, and unless the benches are too wide it does not interfere with the cutting of the flowers or any other necessary routine work.

The usual long list of new Roses for 1890 has been presented by the European growers, and numbers some seventy or eighty sorts, the larger proportion of which are classed among the Hybrids, though the list of Teas is also extended by some twenty-five names, several of which are described as carmine or red in color. It is also stated that a new pink Tea is to be introduced next autumn which is claimed to be far superior to Catherine Mermet. This promised acquisition is of French origin, and has been christened Maman Cochet.

Among the Hybrids, Augustine Guinoisseau will be looked upon with interest. It is a new sport from La France, which is described as being identical with its parent in all respects save in color, which is pure white. If this should prove as good as described it would probably be a valuable variety, but it may be safely estimated that not more than ten of the new Roses of 1890 will prove worthy of general cultivation unless the list has been much more carefully sifted than in previous years.

Holmesburg, Pa.

W. H. Taplin.

Border Pinks and Carnations.

A GARDEN is never too well supplied with these valuable flowers and no plants better repay the trouble necessary in their cultivation. The early Fringed Pinks are of a very sturdy constitution, and the stems being thin and wiry are very little affected by alternate freezing and thawing. The white variety is especially valuable and very fragrant. The Scotch gardeners have originated many fine varieties, which they divide into "show" and "laced" sections, the former being self-colored and the latter having rosy red or purple lacings. They are readily grown from seed, blooming the second season, and a good strain will show great variety in markings, with either smooth or fringed petals. They are fragrant and a large proportion will be double.

The border Carnations follow the Pinks in bloom, and very good varieties may be readily secured the following season from seed sown in the spring, for they seem perfectly hardy the first winter or when in a young state. After the wood becomes heavy and hard they are not reliable, and if it is desirable to save any they should be layered or the tops should be struck after blooming. A good strain of seed should be sown each spring with the annuals, and seedlings should be grown along till fall, when they may be planted in their blooming quarters. A few evergreen boughs make good protection for winter, though this is hardly necessary. In late June such plants will give a wealth of bloom, and though a proportion will prove single, one is sure to secure some attractive double ones. At the worst one can have abundance of bright, fragrant flowers with a good supply of their own foliage—a pleasure usually denied us by the vender of Carnations. If one does not care to trouble with this biennial treatment of the Carnation, some very choice proved varieties may be had from the florists. Of these a good selection would be Old Crimson Clove, or its dwarf variety, Paul Engelheart, Blush Clove, Gloire de Nancy (white), Mrs. Reynolds Hole (salmon), Pride of Penhurst (yellow). The layering system should also be followed with these if certain success is desired.

The "Carnation Grenadin" of the seedsmen is also desirable, being scarlet (of a variety of shades) and usually double.

Elizabeth, N. J.

J. N. Gerard.

Heleniums.—Of North American Composites there are few more valuable for garden culture than these plants. Their flowering season lasts over the greater portion of the summer, beginning in May with *H. Hoopesii*, and ending with *H.*

autumnale late in fall. *H. Hoopesii* is perhaps the showiest and best of all, and should be in every garden of hardy flowers. It is as showy as *Coreopsis lanceolata*, and has stout, erect stems, with numerous large, bright orange-colored flowers, just when no other similar flowers are to be had. The flowers are larger than those of the *Coreopsis*, and as they are of good substance stand well when cut. *H. Bolanderi* is a new species, one of Dr. Bolander's discoveries in north-eastern California, where it grows in low grounds near the coast. This species flowers in June soon after *H. Hoopesii*, and makes a nice succession to that species. The flowers are not as large, but are of a pleasing bright yellow. The ray florets are notched at the end, and give the flower-heads a pretty appearance, not unlike those of the *Gaillardias*. We have noticed some variation in the color of the flowers in a batch of seedlings, some being much darker than others. Both the above flowers have black discs or centres. *H. Bolanderi* is perfectly hardy here, growing about eighteen inches high. It is free flowering and useful for cutting, and like *H. Hoopesii*, it comes readily from seed sown in pots. When large enough these should be planted where they are to flower, for, with *Heleniums*, as with many other herbaceous perennials, the less disturbance during the earlier stages of the plant's life, the better will be the bloom when the flowering period arrives. These *Heleniums* will not flower the first year from seed, but if well treated a quantity of bloom will be produced the second and following years.

South Lancaster, Mass.

E. O. Orpet.

Polemonium pauciflorum, now in bloom from seeds sown early in the year, is a native of the province of Chihuahua, Mexico, and was first offered this year by Mr. W. Thompson, of Ipswich. It is an interesting variety, because other species of *Polemoniums*, with the exception of *P. flavum*, are blue flowered. The flowers of this one are pale yellow in the interior of the corolla and yellowish tinged slightly with red on the exterior. The flowers are funnel-shaped, some two inches long, with a spreading five-lobed mouth, and are produced from the tips of the stems and branches in clusters of from two to eight. The plant forms a bushy tuft twelve to eighteen inches high, with the neat foliage characteristic of the family, and as the flowers are pendent or drooping it is very graceful and attractive, though by no means showy. It is said that it blooms in succession from July to October, and is classed as a hardy perennial, which points remain to be tested. There seems to be no variation among my score or so of plants either in growth or bloom.

Elizabeth, N. J.

Correspondence.
Communal Forests.

To the Editor of GARDEN AND FOREST :

Sir.—The *Rural New Yorker* of July 5th contains a contribution by Mr. Charles Barnard on Communal Forests, a subject which deserves the attention of all persons interested in forestry. Referring to the increasing number of abandoned farms and uncultivated, apparently valueless lands, which in the older eastern states reduce the tax-paying capacity of the township, he suggests that by planting these waste, non-producing lands to forest a revenue might be derived from them. "A man," the writer says, "may not live to grow trees for a crop—a town can, because it is itself immortal. Why, then, should not a township grow timber?"

The suggestion, not novel in itself, is a good one, and should command careful consideration, not only by the friends of a rational forest-policy, but by every citizen who is interested in the prosperous condition of the town in which he lives. If every community will concern itself in the rational use of the land within its borders, if every town and every county will give profitable occupation to its waste lands by utilizing them for forest-growth, the movement would not only increase the financial prosperity of each community, but the efforts of those who work for a rational forest-policy in the country at large would be subserved by every communal forest established. In fact, no better method of forest-reform could be suggested than by beginning forestry in each town, which as a part of the country at large, will influence the movement of the whole. As to the desirability of communal forests—of which we have an example in the first town forest in the United States, at Lynn, Massachusetts—there can be no question.

Whether the method of inaugurating such action on the part of the communities as Mr. Barnard proposes is the proper one need not be discussed here, and whether his plantations would prove profitable as readily as he anticipates is open to serious question. Upon this last point Mr. Barnard himself contradicts his anticipations, for while he figures early returns from

his plantings, he admits at the same time that forestry may not be a business for private enterprise, because of the long time before the investment pays. This is the very bane of forestry reform. If it could be shown as a general proposition that forestry was a paying enterprise from the start or after three to four years' waiting, it would not be difficult at once to interest capital in forest-planting. There may be returns from thinnings, and the farmer who does not calculate his time while cutting and preparing the material which comes from the thinnings, may find a profit thereby; but even in Germany, where labor is cheap and every kind of wood material is used, necessary thinnings are omitted from calculation because "they do not pay for the work." It would be folly for the townships or counties to engage in forest-planting, except with a full realization that they build for the future, and that no returns can be expected within a decade or more.

The case stands differently in communities where the waste and brush lands can be aggregated with some already productive timber-lands into the communal forest, for the returns from the latter part of the property may, under rational management, be made to pay in part for the improvements and superintendence of the remainder. The profitability of forests begins to assert itself only after a considerable period of time and after a large enough area has been brought under systematic management.

It takes, then, years and patient waiting, expenditure at first and rational management, to establish a profitable forest.

That such properties can ultimately be made profitable, even under our present conditions, which differ from those of France and Germany considerably, I have no doubt.

In Germany I know of communities where not only all taxes are paid by the revenue from the communal forests, but every citizen receives a dividend in addition. The town of Görlitz, in Silesia, is an example; also the town of Münden, where one of the Prussian forest-academies is situated. The town of Goslar, in the Harz Mountains, derives from 7,500 acres of forest an annual revenue of \$25,000 to \$30,000, and it may be of interest to American farmers to note that it receives the highest prices for its wood products on account of the excellent roads, which facilitate transportation. The capital invested in making and keeping in order these roads is calculated to yield twenty per cent. yearly on the investment.

From the excellent report of the Forest-master of the City of Zurich (Switzerland), which gives the history of the city forest, going back to the fourteenth century, it appears that the revenue derived from its less than 3,000 acres averaged \$15,000 annually during the decade from 1860 to 1870, and \$18,600 during the next decade. How forest-property under management appreciates in value appears from the following table, which shows in the forests belonging to the canton of Zurich, and comprising about 82,000 acres, during a period of fifty years, almost a threefold increase both of yield and value.

The figures as to yield, expenses and valuation are for a single acre.

Decade.	Gross yield.	Outlay.	Net yield.	Capital value.
1830 to 1840, . . .	\$3.25	\$0.85	\$2.40	\$60.20
1840 to 1850, . . .	3.50	1.01	2.49	61.90
1850 to 1860, . . .	4.59	1.02	3.57	89.24
1860 to 1870, . . .	7.06	1.29	5.77	144.43
1870 to 1880, . . .	8.84	1.87	6.97	174.33

The price now is nine to twelve cents per cubic foot, and sixty to seventy cents per day for wages.

While, then, no move in forestry reform could be more promising than the establishment of communal forests; while eventually these forests will be profitable and sources of handsome revenues, we should not expect the impossible from the forest-commissioners and foresters who shall be called to inaugurate the movement.

Washington, D. C.

B. E. Fernow.

[A full description of the public forest of the City of Lynn or the "Lynn Commonwood," alluded to by Mr. Fernow, has already been given in GARDEN AND FOREST (ii., 526). The early towns of New England held their woodlands and pasture-lands in common, and some 1,400 acres of this land belonging to the City of Lynn now returns to its original character as woodland held in common; but from its position its highest use will be that of a free public pleasure ground.

In an early number we shall publish the first of a series of letters describing the most interesting features of the forest of the City of Zurich, to which Mr. Fernow refers. The letters have been prepared by a young American who is studying forestry in Europe.—Ed.]

'The Evils of Grafting.

To the Editor of GARDEN AND FOREST:

Sir.—As Mr. S. B. Parsons does not approve of Mr. Burbidge's opinions on grafting, may I ask Mr. Parsons, whom I had the pleasure of meeting in America, a few simple questions.

1. I have a number of American Weeping Willows, and in nearly every case the suckers of the common Sallow, on which they are grafted, are springing up and killing them. It is not in the garden proper and I am too busy to keep a man looking out for suckers in out-of-the-way places. Let me ask him if grafting in this and like cases is right. I buy a delicate and graceful tree worked on a vigorous one, which must in time kill it if not carefully watched.

2. I bought one hundred plants of the common *Pyracantha* to form a low fringe above a sunk fence where I wanted the view clear. In every case suckers of the common Quince came up, notwithstanding some care. Does Mr. Parsons think this is right? In our country the Quince grows to twenty feet high. I wanted my *Pyracantha* to spread about as a low Evergreen on the ground and now I must have an eternal fight with suckers or remove the trees.

3. The Ribston Pippin Apple is of so fine a quality that it may be called the most famed of English Apples, but in England the tree is generally cankered and decayed. For a trial I planted it on every stock I could obtain, but I could not in Britain nor in Europe get the plant on its own roots. To get this apple into a vigorous state and free from the canker and decay which affect it would be worth a million guineas to England! Is it reasonable to suppose that every Apple does equally well on the Crab (or what we call the Crab), on which we generally graft? I have seen much to make me doubt it, but I am doing what I can to test the matter fully. I think from Mr. Parsons' long and wide experience and clear observation he will be able to throw some light on these questions.

I could ask other questions of the same kind and I believe his experience of the above mentioned sorts of disaster must be considerable. I am sure he is too reasonable to forget that the question is how the tree behaves in the plantation or garden after it leaves the nursery, and not the convenience of the nurseryman, who puts almost everything on a few easily raised stocks in preference to more natural ways of increasing trees by seeds, cuttings or layers.

Office of *The Garden*, London.

H. Robinson.

I will gladly answer Mr. Robinson's questions, although I see no connection between them and my reply to the strictures of Mr. Burbidge upon a previous article of mine in GARDEN AND FOREST. No intelligent or conscientious nurseryman will think, under ordinary conditions, of grafting a cion upon stock which suckers, or upon stock which is not closely related to it; but many nurserymen dissent from Mr. Burbidge's sweeping assertion that "any fruit-bearing or ornamental tree which will not succeed on its own roots had better go to the rubbish pile at once." They will also object to his assertion that "grafting is always a makeshift, and very often a fraud," as a reflection upon a large body of respectable men. And now for the questions.

1. The American Weeping Willow grows readily from cuttings and can be trained to any required height. I can see no advantage in grafting it.

2. We grow the *Pyracantha* by the thousand for hedges, and grow it by cuttings only. Seedlings will not answer here, for one variety only is hardy, and this will not come true from seed. I cannot conceive why any one should go to the expense of grafting on an unrelated stock like the Quince, or why any one should graft an evergreen tree on the root of a deciduous tree.

3. I do not know the cause of the failure of the Ribston Pippin. It may be an inherent weakness of constitution, and in that case a plant grown from layers would be equally weak. We have similar trouble in this country with the Newtown Pippin, and we overcome it by grafting twice, just as the French do to the Pomme Chataign, a variety which also has inherent weakness. In this double working we have a remedy which it would be unwise to neglect, although it is still more "unnatural" than grafting once. Transfusion of blood may be unnatural, but it has saved human life. If the Ribston Pippin cannot be grown

by double grafting, I would try layering; but the American market could never be supplied in this slow and expensive way.

Of course I can see no reason why plants which take root readily from cuttings should be increased by grafting, and I yesterday found myself very impatiently rooting out some Tea Roses which I had imported from England, and which were budded and overgrown by the stock. Our largest Rose-growers here, who produce 800,000 plants a year of Teas and Hybrid Perpetuals, grow them from cuttings only, and we cannot understand why English nurserymen bud Roses at all, unless it is some sort like the Persian Yellow, which does not strike readily from cuttings.

There is little need of adding anything on the general subject of grafting to what I have already said. Nearly all horticultural operations, even to the transplanting of seedlings, are "unnatural" in one sense. That is, they differ from Nature's ways, although they may not be opposed to Nature's laws. But why should it be called "more natural" to force a cutting to throw out roots than to place it on a stock and allow it to make use of roots already formed? I should use cuttings where they will root readily, because it is easier and cheaper than grafting. I have never observed that a tree from a cutting was more vigorous or long-lived than one from a graft when properly set. Near the spot where I am writing is an Oriental Spruce, which is one of the most beautiful and completely furnished specimens I have ever seen of any conifer. It was grafted forty years ago on a stock of Norway Spruce. Propagation by seed is probably the most "natural," but this is impossible when varieties are to be preserved. I know grafted Apple-trees a century old that are as healthy as any seedling tree. Seedling Apple-trees have sprung up all over the older settled parts of this country, and there are no statistics to show that as a class they are longer-lived than grafted trees. Some die young, some live to an old age, according to their vigor of constitution and the congeniality of their surroundings, and it is the same with grafted trees. I can show Mr. Robinson grafted Apple-trees still in healthy bearing condition which my father planted seventy-five years ago.

Flushing, L. I.

S. B. Parsons.

Low Spear Grass.

To the Editor of GARDEN AND FOREST:

Sir.—I enclose a sample of short grass which almost covers my lawn. It comes into flower and seed when not more than an inch or two high, so that the lawn looks gray and bad for patches of several rods square sometimes. It seems to be a good fighter and able to clean out other varieties and take possession entirely. Please tell me what species this is and what is to be done to exterminate it. It seems to get the best of Blue Grass even. It is certainly much worse here this year than it has ever been before.

Madison, N. J.

R. J.

[The enclosed was a specimen of *Poa annua*, Low Spear Grass, a near relative of June Grass and Fowl Meadow Grass, though differing much from these in habit. It is not a native of America, but comes from Europe. It may grow an inch high, or in new, rich soil a foot high. It loves cool, moist weather, and in damp soil and a cool climate it thrives well in the shade. A little scorching sunlight checks the plants on a dry soil at once and they soon die. Only very small, young plants, if any, live over winter. The blossoms appear very early in spring, probably before those of any other grass. Three or four distinct crops, possibly more, may pass in a single year from the seedling to the seeding plant; but we never heard before that it would crowd out Blue Grass. Professor Beal writes of this grass:

"I had for a long time considered it solely a nuisance on the farm, in the garden or lawn, as it is small and short-lived, but two years ago in August next I saw several lawns under the shade of trees, especially on the south side of Euclid Avenue, in Cleveland, Ohio, largely consisting of this grass. It was not allowed to lack moisture, and

was kept well mown; the light, bright-green color was most charming. There were whole rods of this lawn sometimes in irregular shapes unequaled by anything I ever saw before. There was some June Grass in places and some thin spots where the shade was dense. I did not learn whether this Spear Grass was purposely sown, or whether it had by degrees crowded out other grasses and clovers."

Perhaps the best way to exterminate this Spear Grass is to put the land in fine condition, when with sufficient fertilizer, moisture and light, the small Red Top or June Grass will be able to maintain a good footing against it.—ED.]

Recent Publications.

Elements of Structural and Systematic Botany, for High Schools and Elementary College Courses. By Douglas Houghton Campbell, Ph.D., Professor of Botany in the Indiana University. Boston: Ginn & Co., 1890; pp. 9—253.

It is frequently said, and with some reason, that science is easily learned in these days of abundant and good text-books. No doubt this is as true of botany as of the other sciences, and each new text-book should make the path easier and surer. Unfortunately, there is no royal road to learning, and one result of the great activity of to-day in scientific work, and the resultant specialization of its several departments, is that anything more than an *ipse dixit* knowledge of its general laws is becoming impossible for elementary classes that attempt everything. To lay as good a foundation as is possible for an understanding of such generalizations, most teachers attempt a little laboratory work in one or more directions, in addition to the customary lecture or recitation course. Professor Campbell's book appears to have been written for such teachers.

Inability to cover everything in any such course has given rise to a demand for elementary text-books treating in the simplest manner the practical study of certain parts of botany. Such books cannot, of necessity, be more than introductions to the study, and the courses based on them can be only preparatory to possible future special work in the branch covered. Their use should be possible under the guidance of a teacher of only average ability, or even without a teacher.

Excellent books of this character are both editions of Strasburger's "Botanisches Practicum" and their translations, the botanical part of Huxley and Martin's "Biology," the "Practical Botany" of Bower and Vines, which is an outgrowth of the latter, and the "Handbook of Plant Dissection" of Arthur, Barnes and Coulter. All of these attempt, in a somewhat similar manner, to give a more or less comprehensive knowledge of the structure of selected representatives of the principal groups of plants. The principles of classification of these groups are brought out incidentally in nearly all such books. Physiology is also fairly presented in books of a similar character.

A great stimulus was given to the study of structural botany and the German methods of classification by the publication and translation of the Text-Book of Sachs, nearly twenty years ago, a book which, in its more recent edition, has been divided into several. Some ten years ago Professor Bessey did a good piece of work for teachers by writing his "Botany," largely based on Sachs, and embodying most of its essentials for elementary work, and the needs of still more elementary classes are fairly met by the "Essentials of Botany," subsequently published by the same author.

Each of these books has its uses. None is perfect; but the teacher selects one or the other according to the requirements of the class to be taught. Those of the first group are best adapted to use for teaching methods in connection with a course of good lectures and demonstrations; the others are better adapted to the needs of the student who is to become familiar with representatives of the principal groups of plants and the prevalent basis of classification, when there are few accompanying lectures. Professor Campbell's book belongs to the latter class, rather than the former. It embodies the results of a considerable amount of original work, and contains many original illustrations. That the former adds nothing to the knowledge of the specialist, is no detractor from its merit in this place. The latter are fairly done. In the right hands, the book is likely to prove an acceptable and useful aid in teaching, though it must be admitted that most instructors would have been able to do their work had they been obliged to depend, as in the past, on the older books. It is to be hoped that if it comes to a second edition, the author

will specifically name the plants chosen for illustration, which will involve little additional work, and will remove a cause for just criticism of the present edition.

Shaw School of Botany, St. Louis.

William Trelease.

A *Catalogue of the Plants Found in New Jersey*, being volume two of the Final Reports of the State Geologist of that state, has appeared. It is from the pen of Dr. N. L. Britton, of Columbia College, aided by various specialists, and occupies nearly six hundred and fifty pages, with a full index, which adds to the value of the work. Dr. Britton, as is well known, takes an advanced position on the question of nomenclature, and it is well therefore, perhaps, to reproduce what he says in his introduction on the subject: "The names adopted are based strictly on the principle of priority of publication, the oldest specific or varietal name available being retained in whatever genus the plant is located, or whatever its rank as species or variety. Many of our plants have originally been described in genera other than those now accepted, and many were at first supposed to be species which are now regarded as varieties, or the reverse of this. The method adopted of citing the original author of the specific or varietal name—the only permanent portion of the binomial—in a parenthesis, tells us who first named the plant, while the added name behind the parenthesis shows who first brought the names together in their present combination. This method has, with slight modifications, been generally adopted by zoologists, and by students of fungi, algæ, lichens and mosses, and its general use in botany tends to bring all biological nomenclature into harmony."

Whenever the adopted names differ from those in general use in manuals or class-books of botany, these last are given as synonyms in italics. As a work of reference this catalogue, which is remarkably full in the geographical information it contains, might have been made, perhaps, more useful by the addition of a few references to easily accessible plant-portraits.

The list enumerates: Of flowering plants, 1,919; Ferns and their allies, 76; Mosses, Hepaticæ and allies, 461; Lichens, 329; Algæ, 987; Fungi, 1,705; Protophyta, 164. Total, 5,641.

Similar lists cannot be made too soon for every state, county and neighborhood throughout the nation. We read with regret of the rapid disappearance of many of our wild animals, such as buffalo, elk, deer and Rocky Mountain sheep. In like manner there are many agents at work which have already exterminated a large number of species of plants from entire counties.

Among these destroying agents are the clearing and cultivation of the land and the draining and burning over of swamps and marshes. In many regions fences along the highway have been abandoned, and often the land is cultivated for crops close up to the track of the wheels. The wood-lot is often used as a pasture. In this case the young growth of timber is nearly stripped clean; light enters; grass is encouraged and creeps in. The days of such wood-lots as supplies of timber are numbered; soon the old trees begin to die at the top, make a feeble growth, and the remains are removed for the plow and the meadow. Even along the railways, it is becoming customary to mow or burn the surplus land closely or to cultivate for crops.

In not a few instances the students of neighboring colleges and schools, and members of societies interested in collecting for the herbarium or for their gardens, besides collectors who sell plants to distant nurserymen, all help on the speedy extermination of many interesting plants.

Notes.

By the vote of the school children of New York the Golden Rod has been chosen as the "State Flower." Out of a total of 318,079 votes it received 81,308, while the Rose stood second with 79,666.

The Messrs. Putnam are about to publish a book called "The Trees of North-eastern America," by Mr. C. S. Newhall, with a brief introduction by Professor N. L. Britton, of Columbia College.

Few plants are more useful for the summer decoration of greenhouses than the Tuberous Begonias. Not long ago we saw a house full of these plants from which all the double ones had been rejected, and the effect was wonderfully rich.

The Rose-chaffer, whose depredations are described in another column by Professor Smith, has not been long in learning that the flowers of the great Japanese Lilac are suited to its taste. Wherever we have seen these flowers this season they have been preyed upon by Rose-chafers.

Edward Wakelfield, in his *History of New Zealand*, estimates that the introduction of bumble-bees into that country has already profited the farmers to the extent of \$5,000,000. Before their introduction it was impossible to grow Red Clover seed for lack of fertilizing agents.

In the Boston Public Garden there was lately in bloom a mass of white Ascension Lilies and azure-blue Delphiniums, which presented a most effective combination. The plants seemed informally mingled and they were much more effective from this irregularity.

The new Japanese Poppy Mikado is a really distinct and beautiful flower, the fringe of bright scarlet on the border of the white petals being very effective. It ought to be the parent of a new race of Poppies in which a wider range of colors will be united with the peculiar form of this variety.

In a paper read not long ago before the Rhode Island Horticultural Society, Professor Cushman, apiarist at the State Agricultural Experiment Station, declared that bees never attack sound fruit, but only such as is decayed or has been already injured by other insects; and his words were endorsed by all his auditors.

On one farm of 3,000 acres, entirely devoted to fruit, in Alameda County, California, from \$30,000 to \$50,000 are annually expended in wages. The laborers are in part Chinese and in part Portuguese. The latter are considered much the better workmen, and many of them have already established themselves on small fruit-farms of their own.

Our valued correspondent, Herr Carl Bollé, of Berlin, has long held the position of Chairman of the Division on Trees in the Society for the Promotion of Horticulture. The knowledge and experience thereby implied should render him especially useful in the position recently given him as a member of the Park Commission of the City of Berlin.

The famous old Elm on Boston Common, which fell in 1876, was especially beloved by Methodists, as under its boughs, in the year 1790, the first Methodist sermon ever heard in Boston was preached by Jesse Lee. A centennial celebration of this event was held on July 11th on the spot where the ancient tree used to stand.

Large quantities of compressed vegetables are annually prepared for use in the British army and navy. In addition to separate sorts, a mixed preparation is much esteemed which consists of forty per cent. of potato, thirty of carrot, ten of cabbage, ten of turnip, and ten of seasoning vegetables, such as onion and parsley. The method employed is to dry the vegetables and compress them into small slabs, which are packed in sealed tins.

The season so far seems to have been favorable for the development of forest fungi. The Ash anthracnose (*Gliosporium aridum*), a fungus closely related to the blight of the Sycamore, Oak and Maple, recently noticed in this journal, and the showy white mildew (*Microstoma Juglandis*), which covers the leaves of the Hickory, are both uncommonly frequent. No remedy has yet been discovered which is not too expensive for ordinary application.

In Germany, at least, landscape-gardeners are thought as worthy of honor as artists of other sorts. Not long ago we recorded the various ways in which Lenné's memory has been honored—by the placing of statues and painted portraits in public places and the naming of streets in more than one town. Lenné's most distinguished pupil and successor was Gustav Meyer, who died in 1877, and to him also a life-size statue has now been erected on the terrace of the Treptower Park in Berlin, which was his last work, and is usually thought his greatest.

An esteemed cotemporary kindly attempts to answer our request for information about the Crandall Currant by saying that it is identical with the Missouri Currant, *Ribes aureum*. This fact, however, is one which seems to be universally admitted. The question, originally asked by Mr. Thomas Meehan, is this: How does the Crandall Currant differ from varieties of the same species introduced twenty-five years ago under the names of the Utah Black and Utah Yellow Currants? We should like to know whether these earlier introductions have been kept distinct in cultivation.

The *American Garden* quotes from a western paper the measurements of three Apple-trees. One, which stands in Fairfield County, Ohio, and bears a fruit closely resembling Maiden's Blush, is nine feet five inches in circumference at three feet above the ground, with a spread of seventy feet in diam-

eter. Another, in Wayne County, Ohio, is ten feet four inches in circumference at one foot above the ground, and is known to be seventy-six years old. The third and largest is in the same state, in Washington County, and was planted in 1791 or 1792. The trunk, where it is smallest, girths twelve feet two inches, and the largest branch girths seven feet. It is a seedling, which bears a large yellow apple of excellent quality for cooking.

A German journal reports that about fifty novelties of American introduction were included in the last Chrysanthemum exhibition in London. The writer praises Mrs. Alpheus Hardy very warmly, and says the anticipatory reports were not overcharged except as regards the size of the blossoms, and their smallness he attributes to weakness in the plants caused by excessive multiplication. Among the finest of the other American novelties he notes Medusa, Shasta, Monadnoc (which is especially commended), John Thorpe, Mrs. Andrew Carnegie, George McClure, Mrs. A. J. Drexel, G. F. Moseman, J. C. Price, Beauty of Castlewood and Superbe Flore, which has been introduced in several German cities by an English firm and excited general admiration.

Referring to the note on wire-worms quoted in our last number from *The Garden*, Professor Smith writes that these worms have been for years among those pests for which we had no satisfactory remedies. Salt in corn hills has been used with more or less success, but has killed as many corn plants as wire worms. Experiments made during the present season indicate that in the potash salts, muriate and kainit, we have the long looked for remedy. Laboratory experiments prove positively that both of these substances are fatal to wire-worms, both the myriapods (*Iulus* sp.) and the spring beetle (*Elaterid*) larvæ, while the universal testimony of farmers who have been in the habit of using these substances as fertilizers is to the effect that they have not been bothered since they used them. It will not do to plant in a bed of either muriate or kainit, since the latter especially is dangerous to plant life; but a heavy top dressing some days before planting so that a rain will dissolve and carry the salts into the ground will prove fatal to most of the insects in the soil. Experiments indicate that the muriate is the more effective on insects and the least injurious to plant life.

In a recent number of the *Sanitarian* Dr. W. T. Parker protests against the thick planting of trees very near the house. Not only do they prevent the free access of air and of sunshine or even light, but they also injure the character of the soil as suited for permanent occupation. "A soil," says the writer, "loaded with roots and densely shaded is unfit for man to live upon constantly. . . . Vegetation produces a great effect upon the movement of the air. Its velocity is checked, and sometimes in thick clusters of trees or underwood the air is almost stagnant. If moist and decaying vegetation be a coincident condition of such stagnation, the most fatal forms of malarious diseases are produced. A moist soil is cold, and is generally believed to predispose to rheumatism, catarrh and neuralgia. It is a matter of general experience that most people feel healthier on a dry soil. In some way, which is not clear, a moist soil produces an unfavorable effect upon the lungs. A moist soil influences greatly the development of the agent, whatever it may be, which causes the paroxysmal fevers." Of course in the desire to avoid possible dangers it is not necessary to place a house on an absolutely bare spot, away from any tree, as is often done by rural builders, even when fine trees are within reach. Enough trees to produce an effect agreeable to the eye and comfortably to shade certain portions of the house and its immediate vicinity in summer, yet not so many as to render the soil damp or prevent the free circulation of air, or wholly shut out the sun. This should be the householder's ideal. Conifers are especially bad if many of them stand close to the house, because they exclude sunshine in winter, when one cannot have too much of it.

Mr. B. S. Williams, widely known as the author of the standard work on Orchid culture, "The Orchid Manual," died recently in his sixty-seventh year. He came of a family of gardeners, having worked as a boy under his father (who is still alive at the age of ninety-four) in the gardens of Mr. John Warner, a famous Orchid-grower of the time. His most noteworthy book was the outcome of a series of letters written to the *Gardeners' Chronicle* under the title "Orchids for the Million." It has gone through six editions, and his "Choice Stove and Greenhouse Plants" and "Select Ferns and Lycopods" are likewise esteemed as excellent manuals in their departments. For nearly half a century he has been a successful exhibitor of various classes of plants.

The Chestnut-Tree.

THE Chestnut-tree differs from other trees of the northern hemisphere in the fixedness of its characters. The descendant in direct line of a species which flourished in the Tertiary Period in circumpolar Arctic regions, and which later was widely distributed through the northern hemisphere, it has been affected less during the existing geological era by the surroundings of its home in the three continents than other widely distributed trees; and the Chestnut-tree of North America, the Chestnut-tree of the mountains of the Mediterranean Basin and of the Caucasus, and the Chestnut-tree of Japan, are so nearly identical in all the characters which distinguish one species from another that they may be regarded as the same tree. Other trees of similar ancestry, and especially its nearest botanical relative, the Oak, have varied more or less as their surroundings have favored the development of varied forms, and now the Oaks, the Elms, the Walnuts, the Poplars, the Willows, and the other trees peculiar to the northern hemisphere, have all adapted themselves, by the slow development of new forms, to support the altered conditions which have accompanied the topographical and climatic changes to which the earth has been subjected.

That the Chestnut-tree did not share with other plants to the same degree the power of adapting itself to the altered conditions in which it was placed through the advent and retreat of the coating of ice which covered so much of the northern hemisphere during the Glacial Period, will account, perhaps, for the comparatively restricted area which the genus now occupies and the paucity of its forms.

In North America the Chestnut-tree is confined to the Appalachian region, reaching the coast of New England and the middle states and the northern shores of Lake Ontario; it does not extend into the Florida-peninsula or extend west beyond the hilly region of middle Kentucky and Tennessee. There occurs, however, in North America, where it is endemic, the second species of the genus. This is the Chinquapin (*Castanea pumila*), which has a wider range than the true Chestnut has on this continent, although it does not grow naturally north of Pennsylvania. It extends, however, into Florida and west of the Mississippi River,

where it attains its greatest development. Remnants of what is believed to have been the ancestor of this second species of Chestnut have been recognized in the Tertiary formation of Alaska.

The Chestnut has been so generally cultivated in Europe for centuries that it is not easy to determine how much of its actual distribution there is due to the immediate action of man. It was at one time supposed that the home of the Old World Chestnut was confined to the trans-Caspian regions, and that the Greeks and then the Romans had carried it into Europe. There is reason to suppose, however, that the forests of this tree which cover here and there the mountain ranges from Portugal to the Caspian represent an indigenous growth, a view which would seem to be strengthened by the fact that such forests exist also on some of the mountains of Algeria, where it is hardly probable that the Chestnut-tree was ever cultivated to the extent which the entire naturalization of the species would imply. The Chestnut is common in central Europe as far north as Britain; but it is reasonably certain that it was carried there by man in comparatively recent times. West of the Caucasus there is a long stretch where the Chestnut-tree has not secured a foothold. It is not found in the forests of the Himalaya or in China, although it is more than probable that further investigation of the flora of the mountain regions of the western part of the empire will bring to light the presence of forests of Chestnut-trees similar to those which occur in Japan.

The Chestnut for centuries has been one of the most valuable food-producing trees of Europe, and the most careful attention has been paid in Italy and France to developing the size and improving the quality of the fruit. The Romans, in Pliny's time, distinguished eight varieties of chestnuts, and now the number of recognized varieties is very large. The cultivated chestnuts are divided into two classes, known in France as Marrons and Chataignes, the latter bearing about the same relation to the former as the crab-apple does to the apple. Marrons are larger, more farinaceous, and much sweeter and more aromatic than the ordinary chestnut, and are the result of careful selection and cultivation, which has been going on for centuries. Marrons of the best quality are produced in central and southern France, although it is in Italy that the chestnut is more used as an article of food than in other parts of the world.

The Chestnut must be considered one of the most important North American deciduous trees, although several others grow over a much larger area and some of them attain to larger dimensions and produce more valuable timber. The Chestnut-tree, however, grows in America to a respectable size, and specimens often occur on the slopes of the southern Alleghany Mountains with trunks four or five feet in diameter. It is never, however, a very tall tree here, rarely attaining the height of a hundred feet. The trunk is generally short, dividing at a distance of twenty or thirty feet from the ground into stout spreading branches, which form a handsome, compact round head. The habit of the tree is well shown in the illustration on page 359, which represents two characteristic Chestnut-trees, as this tree often appears on the hill-sides of New England.

The fruit of the American Chestnut is small, but very sweet, and it shows a tendency to vary considerably in size and quality, showing that time and care only are needed to produce varieties which will equal in value the best Marrons of France. The production here of the best varieties of chestnuts, however, can be obtained much more quickly by the introduction into the country of European varieties than by the slow process of selecting and developing the native fruit. The European Chestnut, to be sure, is not perfectly hardy in the northern parts of the country, but it flourishes, however, and produces its fruit in the middle and southern states. The population of North America is still too scanty and food is too abundant here to make the cultivation of the Chestnut-tree on any large scale a practical undertaking at present; but the time

will come when the mountain-sides of all the Alleghany region, from Pennsylvania to Georgia, will find their most profitable employment in the production of chestnuts for food. There is no part of the world which is better suited for the purpose, or one in which the Chestnut-tree flourishes with greater luxuriance.

The Chestnut-tree, too, produces wood of great value. Chestnut is one of the American woods best able to withstand the effects of decay when placed in the ground. This makes it one of the best woods for fence-posts, and it has no superior for railroad-ties, for which purpose, especially in New England, it is largely used. It is also used sometimes in cabinet-making. The coarse grain and large open ducts peculiar to this wood unfit it, however, for this purpose, and it is now less generally used than it was formerly in this way or in the construction of dwellings.

The value of the Chestnut as a timber-tree is increased by the fact that the stumps of cut trees have unusual power of producing shoots which soon form trunks large enough for posts and railway-ties, so that a forest of Chestnut-trees may be cut over every thirty or forty years and continue productive during several generations. The American Chestnut possesses a great deal of value as an ornamental tree. It grows rapidly even in light, porous drift, and soon makes a handsome round-headed specimen. It is very beautiful when it is covered early in July with its showy yellow flowers, whose odor some people find, however, extremely disagreeable. Few insects prey upon its handsome glossy foliage, and the fruit, which grows and ripens in the short period of about two months and a half, possesses, even in its unimproved condition, considerable money value.

THE Census of this year naturally suggests the subject of the increasing density of population in this country, and it is encouraging to see any disposition to recognize and consider difficulties and problems which may arise from this source. Until very recently the people of this country have been unwilling to admit the necessity of foresight or self-restraint in any direction. Wastefulness has been regarded as an indication of broad and generous qualities, and it has become a prominent feature in the national character. All our possessions have been considered inexhaustible and have been treated accordingly. We have slaughtered and devastated whatever belonged to the nation, our soil, forests, fish and game, out of mere wanton destructiveness and folly worse than barbaric.

We shall reap what we have sown. When forest-conditions are destroyed on mountains and hills, and the soil has been swept away in consequence, it can never be restored. We live in a world where means and conditions are necessary for the production of results, and we might as well at once begin to depend upon calling our food out of the air by magic as to expect that an unlimited population will be able to obtain the means of subsistence from soil of which the fertility is steadily diminishing.

A recent writer says that the point of the whole matter is that the children of the public schools should be taught the necessity of better cultivation of the land on account of the prospect that in the future population is likely to press upon the means of subsistence. He thinks if this is done we may rest content for the future, because the Anglo-American race has shown itself equal to the solution of all the problems it has ever been called to face. But if the people of this country would begin the practice of such methods of living as are required by the conditions and circumstances of our own time, it would probably have a better effect on the children than any amount of theoretical teaching in the schools. What good will it do to talk to the children about the forestry interests of the future when they see around them every day the prevailing barbarism, the general disregard of the very things which they are told they should attend to when they are grown up? Until our towns begin to treat groves and trees along the roadsides and in other public places in a civilized manner,

until the different states and the nation adopt a policy of intelligence in dealing with public forest-interests, mere talk in the schools about forestry and agriculture would have little value or vitality. We can hardly hope to escape from the obligation to act sensibly and decently ourselves in the present, in our treatment of these great, important matters, by establishing in the schools instruction regarding what should be done in the future. The time for action has already come, and the need for it is pressing. Example is the best teaching. But it is easier to talk about the duty of another generation than to perform our own.

The Preservation of Natural Scenery.

SOME weeks ago we gave an account of a meeting held in Boston to secure the preservation of beautiful and historical places in the state of Massachusetts through a board of trustees empowered to acquire real estate which possesses natural attractiveness and historical interest and to hold this free of taxes for public use. Mr. Charles Eliot added a report upon this proposition, which covered the question so thoroughly that we will do our readers a service by presenting a brief abstract of it. It set out with the assumption that all were agreed upon the value to a crowded community of easily accessible scenes of natural beauty and romantic interest; that cultivated people had none of that selfish feeling which sometimes suggested that it might be preferable to allow a favorite grove or brook-side to be destroyed rather than to help open it to the enjoyment of the "vulgar throng"; that everybody desired to see as many refreshing and interesting spots as possible dedicated to the public enjoyment of our own and future generations. England is strewn with public commons and public forests which are the remnants of ancient royal hunting parks. Moreover, public foot-paths everywhere lead across private land, and many of the grandly wooded estates of the country are open to all who care to enter. Every town has some attractive place of common assemblage, such as the river banks at Lincoln or Durham, the castle grounds at Ludlow or the city walls in Chester. In short, no such problem confronts the people of England as that which faces the men of Massachusetts. Even the French Republic maintains public forests and the once imperial gardens and palaces with a care which is hardly excelled in imperial Germany. New England once possessed considerable commons, but they have long since been appropriated to private use.

There is a Public Forest Act which may help to secure large tracts of land for the enjoyment of the people, as it already has done in the city of Lynn, where a wilderness of 1,500 acres has been converted into a Commonwood, and under this act it is hoped that the towns which surround the Middlesex Fells may secure as large a tract as the Lynn Public Forest. But no easy way exists at present by which small bits of natural scenery and single buildings or sites of uncommon interest can be dedicated to public use. These places might be taken by towns under the Park Act, but the government of a Yankee town is not always adapted to the maintenance of trusts which require good taste and permanent policy. The desired result could be reached by a special act of the Legislature as was done in the case of the old South Church in Boston and by the inhabitants of Cazenovia, New York, in order to secure the gorge and falls of the Chittenango. But the necessity for special laws and the organization of special boards discourage and hinder those who have this cause at heart, and, therefore, the plan of a single board of trustees for the whole state was proposed by the committee.

Scattered throughout the state are thriving historical and antiquarian societies and other associations which have already saved some memorable places. The Essex Institute has purchased a great boulder called the Ship Rock. The Old Colony Natural History Society owns Dighton Rock and the Worcester Natural History Society owns part of the shore of Lake Quinsigamond. If these societies, with all other individuals who may be interested, should make appeal to the Legislature to establish one strong board of trustees, this concerted action would probably bring about the creation of the board; and the existence and action of this board would in turn stimulate local effort for the acquisition of desirable lands. On a similar plan some of the noblest institutions of the state have been maintained, like the Massachusetts General Hospital and the Boston Museum of Fine Arts. It may be asked whether the value of natural beauty and historical memorials is sufficiently understood in the state to encourage gifts of such a character to the trustees. The value of a hospital is recognized, but is the same true of the love of nature and of the historical past? This ques-

tion can only be answered by experiment and the committee have no doubt of the result.

It is encouraging to recall the fact that what is now desired to be accomplished throughout the state by a central board of trustees has already been gained in a suburb of Boston by the Board of Trustees of Harvard University. This board once acquired, by gift from Benjamin Bussey, a large tract of farm and wood land in Roxbury. By virtue of their charter, the Harvard trustees hold this land free of taxes; and when, in pursuance of the will of James Arnold, they established on a part of it a collection of all the trees and shrubs which will live in this climate, they made with the city of Boston the same bargain which it is now proposed to enable the suggested board of trustees to make with any town or city in the state. Harvard University opens the Arnold Arboretum to the public in return for police protection and the making of roads and paths.

Unripe Seed.

AT this season of the year it may be desirable to call attention to some past work done at the New York Agricultural Experiment Station, which seems to have been strangely overlooked, important as it may be in furnishing clues and suggestions toward a method of attaining earliness and other changes in our cultivated vegetables. Last summer Professor Arthur, of Purdue University, gave me an oral account of the great success attained in earliness from the use of Tomato seed from the strain originated at Geneva from unripe seed, a strain for which we had many applications from practical growers; and perhaps Professor Goff may be induced to give to the public the results of his continuous work in this field.

In 1883 it was found that Flint Corn, Sweet Corn and Dent Corn, harvested before glazing, germinated freely, and that Peas planted while at the edible stage vegetated freely. (Report of 1883, 39.)

In 1884 ripe and unripe seeds of the Early Dutch Turnip were planted. Fifteen roots from the green seeds weighed on the average four and a half ounces each; thirty-four roots from the ripe seed averaged six ounces each. (Report of 1884, 199.)

Very green seeds of Cook's Favorite Tomato yielded ripe fruit in 126 days from planting; ripe seed yielded ripe fruit in 146 days from planting. The first ten ripe fruits were gathered in 137 days from the green-seed plants; in 152 days from the ripest-seed plants. For additional particulars the reference may be consulted. (Report of 1884, 224.)

Trials were made with three varieties of Peas. The first pods were ripe in the Blue Peter in sixty-eight days from both the ripe and unripe seed; in the case of the Eugenia in seventy-seven days from ripe seed, in seventy-two days from green seed; in the case of William the First in sixty-five days from the ripe seed, in eighty-four days from green seed. The number of pods per 100 plants varied from 629 to 467 between the plants of Blue Peter from ripe and those from green seed; from 706 to 677 for the Eugenia; from 300 to 1,600 for William the First. (Report of 1884, 232.)

In 1885 green seed gave heads of Danish Drumhead Cabbage ninety-seven ounces in weight; ripe seed seventy-five ounces. (Report of 1885, 154.) In Lettuce no difference was observed between green and ripe seed.

In the Tomato, a gain for the first ten fruits of a week was noted in favor of immature seed, in one case, and with another variety unripe seed produced fruit considerably earlier.

These references should be enough to turn attention to the experiments. The best results were with the Tomato. Here a gain of fifteen or twenty days in earliness was obtained, and this gain, as Professor Arthur tells me, has been maintained to date. A weakness in the plants has been a serious drawback, and while green seed seemed unfitted for immediate use by the grower, yet it is by no means certain but that this feebleness may be trained out by the experimenter. The trials were too few to attain certainty, but the great value to marketmen of an early strain of seed ought to encourage further tests. Why should not our experiment stations enter upon this interesting and promising inquiry?

South Framingham, Mass.

Is the Strawberry Improving?

THE history of the cultivated Strawberry, though short as compared with that of most of our fruits, is of especial interest as bearing upon fruit improvement. We have here a fruit that possesses such rare dessert qualities that it is a universal favorite, a fruit of which seedlings are grown with the utmost ease, and come very quickly into bearing, and of which several botanical species hybridize very readily, produc-

ing abundantly fertile offspring. All these facts have tended to concentrate the attention of amateur horticulturists upon the Strawberry, and it is not improbable that more seedlings of this fruit have been grown during the last half century than of all other fruits combined.

What has been the result? Has the Strawberry shown a continuous improvement during this period? Hovey's Seedling was introduced about 1834, and through its sterling merit soon became a standard. The last report of the American Pomological Society shows that this old favorite is still grown in sixteen states, and in only eight of the fifty-three tabulated varieties is it excelled in the number of its stars. The first supplanter of Hovey's Seedling in public estimation was the Wilson, of which the date of introduction seems to be lost. From the report just cited it appears that this variety is still grown in thirty-eight states, and the number of its stars surpasses that of the next highest by nearly 100 per cent. In 1872 Downing described 260 varieties of Strawberries, of which only eight were named in the last report of the American Pomological Society. The question which naturally follows is: Have any varieties developed since the last meeting of the American Pomological Society that are likely to surpass the Wilson in public esteem? It is true that this old standard is suffering seriously from disease in many localities, but where maintained free from disease it certainly has not yet been supplanted. Unwilling as we may be to admit it, these cold facts declare that since the appearance of the Wilson not one of the millions of seedlings that have been grown has surpassed it in excellence, all points considered.

Do these facts imply that further attempts at improving the Strawberry are useless? Not necessarily. It is much to be regretted that we do not know more of the history of our cultivated Strawberry. The common opinion of horticulturists and botanists appears to be that it is the result of a hybrid between our native *Fragaria Virginiana* and the *F. grandiflora* of South America. But by whom the importations of the latter were made or by whom the hybridizations were effected is not definitely known. If all the amateur Strawberry work of the past half century has been confined to the posterity of one or a few hybridizations between the two parental species, it is not strange if the limits of variation have been reached. Unless we accept the hypothesis that hybridization tends to reproduce all past variations within the parental families, it is possible that by securing new hybrids between the species that are the parents of our cultivated Strawberry, selecting specimens that show marked characteristics, the scope of variation might be very much extended. It is hardly probable that the original parents were selected with any great degree of care or wisdom, but the results have proved infinitely valuable. Possibly a more careful selection of parental types might give rise to much greater improvements.

The importance that the Strawberry has assumed as a commercial fruit is certainly sufficient to warrant a systematic series of experiments looking toward its further improvement, and in these days of experiment stations, why should not this be undertaken?

Notes on North American Trees.—XX.

Description of the Wood of Certain Species.

Terminalia Buceras. Wood exceedingly heavy and hard, compact and close-grained, containing numerous minute evenly distributed open ducts; layers of annual growth hardly distinguishable; medullary rays thin, very obscure; color light yellow-brown, sometimes slightly streaked with orange, the sap-wood clear pale yellow; specific gravity, 1.0490, 1.0322, average 1.0406; ash, 4.93, 4.84, average 4.89; weight per cubic foot, 64.85 pounds; fuel value, 0.9868. Collected by A. H. Curtiss and C. S. Sargent on Elliott's Key, Florida.

Quercus tomentella. Wood heavy, hard, close-grained, compact, satiny, containing broad bands of open ducts parallel with the broad, conspicuous medullary rays; color pale yellow-brown, that of the sap-wood rather lighter; specific gravity, 0.7187, 0.7240, average 0.7214; ash, 1.10, 0.90, average 1.00; weight per cubic foot, 44.95 pounds; fuel value, 0.7142.

Cupressus MacNabiana. Wood light, soft, very close-grained, compact, bands of small summer cells narrow, dark colored, conspicuous; medullary rays thin, obscure; color light brown, the sap-wood nearly white; specific

gravity 0.5503, 0.5647, average 0.5575; ash 0.61, 0.65, average, 0.63; weight per cubic foot, 34.74 pounds; fuel value, 0.5540. Collected by T. S. Brandegee in Lake County, California.

Picea Breweriana. Wood much heavier than that of the other North American species, soft, close-grained, compact, satiny; bands of small summer cells broad and conspicuous, resin passages broad, widely scattered, conspicuous; medullary rays thin, numerous; color very light brown or nearly white, the sap-wood hardly distinguishable; specific gravity, 0.5179, 0.5103, average 0.5141; ash, 0.44, 0.53, average 0.49; weight per cubic foot, 32.04 pounds; fuel value, 0.5116. Collected by T. S. Brandegee on the Siskiyou Mountains, Oregon.

Larix Lyallii. Wood heavy, hard, close-grained, compact, susceptible of a fine polish; bands of small summer cells broad, occupying from a third to a half of the layers of annual growth, very resinous, dark colored, conspicuous; resin passages few, obscure; medullary rays numerous, thin; color bright reddish brown, that of the sap-wood nearly white; specific gravity, 0.6785, 0.7369, average 0.7077; ash, 0.30, 0.25, average 0.28; weight per cubic foot, 44.10 pounds; fuel value, 0.7057. Collected by T. S. Brandegee in Washington Territory.

The wood of this species is intermediate in weight between that of the eastern Larch (*L. laricina*) and that of the western Larch (*L. occidentalis*), which surpasses in weight and strength the wood of any North American coniferous tree.

Sabal species. Wood exceedingly light, soft, fibro-vascular bundles broad, light colored, not very conspicuous; color light brown, tinged with red; specific gravity, 0.2679, 0.2534, average 0.2607; ash, 3.74, 3.63, average 3.68; weight per cubic foot, 16.25 pounds; fuel value, 0.2511; used for piles, wharves, etc. Collected by C. G. Pringle near the mouth of the Rio Grande in Texas.

C. S. Sargent.

New or Little Known Plants.

Æsculus Parryi.*

A DWARF Horse-chestnut detected on the shores of Todos-Santos Bay in April, 1882, by a party of botanists consisting of the late Dr. C. C. Parry, Mr. C. G. Pringle and Mr. Marcus E. Jones, was described under this name by Professor Asa Gray in the *Proceedings of the American Academy of Arts and Sciences* (xvii., 200). He pointed out the affinities of the plant, a low shrub, with the familiar Buckeye of California, which in many respects it closely resembles. The chief differences are found in the character of the calyx, which in *Æsculus Californica* is deeply two-lobed, the lobes being very slightly divided, while in *Æsculus Parryi* the campanulate calyx has five nearly equal lobes. These characters are constant in all the species I have examined, and I fail to find any intermediate form which would serve to connect the plant of Lower California with the California Buckeye, from which it differs also in its shorter inflorescence, its shorter pedicels, smaller flowers and fruit, and in the dense pubescence which covers the under surface of the small obovate leaflets, which are sessile, or generally nearly so. The fruit is unarmed, obovate, rather less than an inch long and broad, in the specimens I have seen, which are from one to three-seeded. The seed is a third of an inch in diameter.

This interesting plant (see page 357) has not been introduced yet into cultivation.

C. S. S.

The California Pæonias.

OUR continent seems to be popularly credited with only a single native species of Pæonia. In one of several valuable paragraphs on the genus by Mr. Watson, of London, published in a recent issue of GARDEN AND FOREST, I read the following in relation to America: "In the latter country *P. Brownii* is the only species that occurs wild."

* "ÆSCULUS PARRYI.—Æ. Californicæ affinis, frutex humilis; foliis 3-5-foliolatis; foliolis obovatis obtusis subcoriaceis brevissime petiolulatis subtus cano-tomentosis; floribus brevipedicellatis; calyce campanulato ad medium usque æqualiter 5-fido petalisque extus tomentosis; filamentis validioribus minus exsertis."

The truth is, that we have two easily distinguishable species, both belonging to the Pacific slope of the continent, and both found within the limits of the extensive commonwealth of California, although inhabiting each its own peculiar climatic region, neither one intruding upon or even nearly approaching the territory of the other species. Neither one is of recent discovery; but in the herbaria of eastern America, as well as in those of Europe, if both species occur, authors have apparently confounded them. The names of the two, as well as their distinguishing marks, may be given thus:

Pæonia Brownii, Dougl. (Hook., Fl. Br. Am., i. 27.) Herbage glabrous and glaucous; leaves of ovate general outline, ternately divided into many short obtuse segments.

Pæonia Californica, Nutt. (Torr. & Gray, Fl., i. 41.) Glabrous, but not glaucous; leaves twice or thrice as large, of rounded and pedate general outline—i. e., broader than long, divided into few lanceolate or oblong-acute segments.

P. Brownii inhabits the subalpine regions of the snowy mountains, from middle California northward through Oregon and Washington, flowering in June and July, often near banks of melting snow.

P. Californica, at its northern limit, is separated by 200 or 300 miles at least from the nearest habitat of its congener, flourishing in a climate almost as different as possible. It belongs to the hill country of southern and sub-tropical California near the sea, where snow never falls and where its shoots appear above ground and push into bloom soon after the first of the late autumnal rains.

From some of the specimens in my herbarium I suspect these plants will prove further distinguishable by different subterranean characters. While the vegetating shoots of *P. Californica* seem to arise immediately from the midst of a fascicle of (tuberous?) roots not deeply seated in the ground, those of *P. Brownii* are attached to the summit of a thick, somewhat ligneous root-stock, which may or may not be found to connect with a deep-seated fascicle of roots. Since the time when I learned to distinguish the two species at a glance in even the poorest herbarium specimens, I have had no opportunity to take up the subject of their vegetative characters. Neither species is in cultivation anywhere so far as I know, and my location is midway between the respective habitats of the two, and far from that of either one. The flowers of both are small, of a dark dull red, without beauty; but the botanical interest of these species should make them desirable wherever the genus is extensively cultivated, whether for botanical or horticultural purposes, though botany and horticulture ought to go more hand-in-hand than they have done.

Edward L. Greene.

Foreign Correspondence.

Botanical Gardens at Birmingham.

IN some of the most important of English provincial towns there are pleasure gardens called botanical gardens, for which a price of admission is charged and where a more or less interesting collection of plants is included amongst the attractions of the place. These attractions may vary from a brass band to a company of performing minstrels or a bicycle match. As a rule, the collection of plants scarcely justifies the title of the gardens, and in some there are as few evidences of good horticulture as of botany.

The botanical gardens at Birmingham are, however, a striking exception—the plants, both in-doors and out, being particularly good, both in regard to their variety and cultivation. The gardens are small, occupying only about twelve acres, but their position is a well chosen one. They are on the side of a slope, commanding a view of beautifully wooded country. "On the right is to be seen the village of Harborne, backed by the Warley Woods, and on the left the eye follows the little valley of the Bourn, and beyond are the hills of Bromsgrove Lickey. Harborne was long the residence of David Cox, the painter, but it is strangely altered since the time when he was laid to rest under the Elms in the old church-yard."

The plan of the gardens was prepared by J. C. Loudon, and they were opened to the public about sixty years ago, under the auspices of the Botanical and Horticultural Society of the town. There is a charge for admission, and a string band performs in the afternoons during the summer.

A students' garden is one of the features of the place, where the plants are arranged in their natural orders for the convenience of the students of Mason College, in the town, and others. A similar garden has long been provided at Kew. Students are allowed to gather specimens of any of the plants they wish to examine or preserve. This arrangement is greatly

appreciated by hundreds of those who visit Kew for purposes of study.

Amongst the most striking of the plants noticed by me recently, when looking over the gardens at Birmingham, the following deserve special mention :

Tree Ferns are well represented, and comprise some unique

luxuriance are generally treated as stove or intermediate species. There are *Cyathea princeps*, *C. spectabilis*, *C. funebris* and *C. medullaris* represented by tall-stemmed, large-headed specimens. Cibotiums were equally striking; as were *Alsophila excelsa*, with a stem fifteen feet high ; *A. australis*, twenty feet high ; *Lomaria gibba*, *Dicksonia squarrosa*, a pair, twenty feet

Fig. 47.—*Esculus Parryi*.—See page 356.

examples of rare species. They are grown in a tall octagonal house along with Camellias, Lapagerias and other typical greenhouse plants. I mention this fact as conclusive evidence that the Ferns receive ordinary greenhouse treatment all the year round. In winter the temperature frequently falls to forty degrees Fahr. Unless I am very much mistaken some of the Ferns which are growing in this house in perfect health and

high ; *D. antarctica* and *D. Lathamii*. This last is supposed to be a hybrid between *D. antarctica* and the rare *D. arborescens*, a native of St. Helena. Mr. Latham, the curator of the gardens, raised this plant from spores at a time when he had growing together the two species from which it is supposed to have originated. It is a very distinct Tree Fern, quite unlike any other known in gardens. The stem is seven

feet high, two feet through at the base, and it bears an enormous head of fronds, each about twelve feet long, with large, leathery gray-green pinnules. The base of the rachis is clothed with long silky scale-hairs of a deep golden brown color, a character which led to the plant's being mistaken for *D. chrysotricha*. Young plants show an equally well marked individuality. It is becoming quite evident, to me at any rate, that a large number of Ferns, and especially arborescent Ferns, are cultivated in much warmer houses than they require or even than is good for them. The finest collection of Tree Ferns is probably that in the Brussels Botanical Gardens, where species from all parts, temperate as well as tropical, are cultivated in a large house wherein the conditions are those of a warm greenhouse rather than a stove.

A fine glass structure about 100 feet long by forty feet wide, and about twenty feet high, is used as a promenade and exhibition hall, at Birmingham. Stages run all round the sides, and these are filled with plants, chiefly ornamental, whilst from the roof hang creepers of various kinds. A band stand at one end of the structure is partly hidden by a group of Palms, Musas and other fine leaved plants. The entire range of the stages along one side of this house was at the time of my visit filled with a collection of Fuchsias, some of them trained a little way up the roof, others hanging gracefully over. The effect was particularly good—an irregular wall of masses of flowers all hanging elegantly as Fuchsias only do hang. In addition to such fine varieties as Golden Avalanche, Mrs. Marshall, Earl of Beaconsfield, Mrs. G. Rundell and Monarch, such handsome species as *F. corymbosa* and *F. arborea* were conspicuous. In another house were some beautifully grown examples of *F. triphylla*, the pretty Mexican species which was brought into notice by Kew some six years ago. It is the species upon which the genus was founded, but so little was known of it that botanists began to suspect that the type of the genus was not a Fuchsia at all! Mr. Latham obtained a plant of it from Kew, as also did many others, but whilst they and Kew have been struggling with the plant in a greenhouse and grown it but poorly, here at Birmingham it has grown very freely, forming perfect specimens two feet through and profusely covered with large clusters of its bright scarlet, long-tubed flowers. The secret of Mr. Latham's success with this plant is stove instead of greenhouse treatment.

Mitraria coccinea is grown well as a wall plant in a lofty greenhouse. The brilliant color and elegant form of the flowers of this easily grown plant merit better recognition for it than it receives at present. It is grown in pots at Kew and forms handsome specimens.

Clerodendron fallax is exceptionally well managed at Birmingham. As a rule it is straggly and thin in habit, but here it is fully a yard through, thickly clothed with large dark green leaves, whilst each of the eight or ten branches bears a head eight inches through of bright scarlet flowers. The plants continue in bloom at least two months. At Kew there is a white-flowered variety (*C. fallax alba*) of this fine old-fashioned stove plant.

The collection of Orchids comprises not a few choice and rare kinds amongst a fairly comprehensive lot of popular garden sorts. Instead of growing them in houses by themselves, Mr. Latham mixes them with miscellaneous flowering plants and Ferns, an arrangement which enhances the beauty of the Orchid flowers and improves the appearance of the plants.

Callicarpa purpurea is splendidly grown by Mr. Latham. Whilst it is hardy enough to grow in a cold greenhouse, this shrub is never seen at its best unless when grown in heat. At Birmingham it occupies the central stage of a house where Gloxinias, *Aristolochia elegans* and *Hoya globulosa* are at home, the *Callicarpa* forming shrubs six feet through with branches fully four feet long, leafy from base to point, and with a cluster of flowers or small berries in every leaf axil. In autumn the berries will be about the size of Peas and colored bright magenta.

Platycerium Stemmaria is a very striking Fern when grown well, as it is at Birmingham, where some large examples occupy a portion of a house devoted to choice Aroids, Crotons, Dracænas, etc. In the greenhouse, along with the Camellias are two enormous masses of *P. alcicorne*. Apparently this species is perfectly happy in a greenhouse. *Ouvirandra*, *Nymphæas*, *Todæas* and other Filmy Ferns, *Stapelias*, Cacti and some of the most important of economic plants are also in this collection. Altogether the Botanical Gardens of Birmingham must play a not unimportant part in the education of the people of the town, as well as affording a very pleasant resort for leisured people at all times of the year.

The Endurance of Orchards.

IT is a very common remark that our modern orchards do not live so long as the orchards of our fathers and grandfathers. There is truth in the statement. Those old orchards were usually seedling trees, picked up in the fence corners, planted in sod, sparingly pruned, slow to come into bearing, and to a very large extent ungrafted, and producing little other than cider apples. I was reared in a ten-acre orchard of this sort, and having followed fruit-growing nearly ever since, I think I can explain why our modern orchards are shorter lived than those of our forefathers.

Those old seedling trees, picked up wherever the scattered seeds found a hospitable spot, were rarely transplanted to the orchard until six or seven feet high—which means at least as many years of age. Set out in sod, they re-established themselves slowly and grew slowly, so that few of these orchards came to full bearing in much less than twenty years. In those days there was little market even for good fruit, and but few trees were grafted with the better kinds in cultivation—hardly more than enough for home use. Cider and cider brandy were the objects sought by the orchardist then.

The old-time orchardist was not a skillful pruner; his implement was the axe; but he only pruned to get rid of limbs that were in his way. Land was cheap and the trees were allowed plenty of room. The soil was fresh and they grew thriftily—such wounds as they received healing quickly. Selection had given only the most vigorous of the abundant seedlings a place in the orchard, while the winters had sufficient time, before these were transplanted, to winnow out the weaklings. So the old orchards, started with strong trees, in good soil and widely spaced, grew up with but slight pruning under the very best conditions for a long existence.

Contrast all this with our present method of planting an orchard. Beginning with two or three-year-old trees from a highly enriched nursery, we find nearly all but the few skilled professional orchardists planting these trees in the grass, as of old. The papers are full of advice about pruning fruit-trees, and the jack-knife and saw are allowed free play on these younglings before they have got fairly to growing. The injury in cutting a tree is in direct proportion to the amount of wood removed, relatively to what is left, and it too often happens that the ignorant pruner administers a life-long check to his tree in the first years of its life. Such a tree struggles along feebly, it may be for many years, but at last dies without ever yielding any profit to the planter.

On the other hand, it may be that the would-be orchardist sets his trees in an enriched piece of tilled land. This is right, if his selection of varieties is right. But the ease with which trees can be had from a distance, and the persistence with which new varieties are pressed upon the public, too often lead to a heterogeneous collection of sorts, few of them well suited to the place in which they find themselves. There are very few cosmopolitan Apples. Many sorts are very local, and however fine or profitable in the right spot they are unthrifty in every other. The old orchards were native to the spot and their trees were well winnowed by the seasons before they were admitted to cultivation.

We must admit that the old orchards were vigorous and long lived, and for the times and uses when and for which they were planted, they were profitable. A modified form of the old method still continues in many places. Most of the commercial orchards of Maine are grafted upon seedlings selected and set out as above detailed, and the practice is not confined to Maine. It is in many places, especially in the north, better than purchasing from nurseries, because the stocks are tested for hardiness before the grafting is done. Many of our best market Apples are too tender in Maine to be profitable, unless top-worked upon stocks more hardy than themselves.

This brings one to another reason why orchards in many places, though productive for a while, are not enduring. These orchards consist of sorts not quite hardy enough for the spot where they grow. Top-worked upon native seedlings, they do well for a while; but severe test winters, in conjunction with heavy crops of fruit as they come into full bearing, weaken the vitality of the grafts; and with a hard winter, immediately following a large yield of fruit, the orchard is found in a bad, and often an irrecoverable condition. There is nothing in such a result that should be unexpected to an intelligent cultivator. If he wants a long-lived orchard he must plant only such long-lived varieties as are quite capable of enduring the severest extremes of the locality. But I believe it will often pay sufficiently well to practice the other method, though

Typical New England Chestnut-Trees.—See page 358.

inevitable risks attend it. The orchardists of south-western Maine grow such valuable commercial apples as the Baldwin, the Rhode Island Greening, the Roxbury Russet and the Gravenstein successfully only when top-worked upon hardy native stocks. Handy to Portland and to Boston, these growers have easy access to the best home and foreign markets with their apples, which, when well grown and properly handled, have a quick and sure sale at a high price. Their trees will not be long-lived, but they will live long enough to yield a handsome profit; and as they rarely die all at one time, the orchard can be kept up by replanting, or by successive plantings, so as to make the business continuous. Such orchards, short-lived though they may be, are very much more profitable than their long-lived predecessors. We can still have long-lived orchards by reverting to old methods. In changing from them we have not effected any change in Nature. She will still give us all that she gave our fathers if we will comply with her conditions.

Our Currants.

THE currant crop should be one of our largest. The market is always good. The demand is never met by the supply. I never fail to obtain eight cents a pound, and this year have marketed all my crop at ten cents. The fruit pays at five cents a pound. The bushes need strong, moist, but not wet, soil. They should be kept clean and in a high state of culture, but they like partial shade. I grow them in the same rows with red Raspberries, alternating the bushes.

The varieties best for market are Versailles and Fay. There is little difference between these, and the preference is for Versailles. This Currant is not easily obtained—that is, the genuine. It is magnificent in bush and bunch. Why Fay ever secured such applause as superior to all others is a wonder. It is hardly distinguishable from the Versailles. The Cherry has a short bunch, some years very short. It is also a comparatively poor cropper, and is not well flavored. The sweetest currant is White Dutch; but when not very well grown it is over seedy and small. White Grape is the first of all currants for the table. It is thin-skinned, not over seedy, large, handsome, with superb bunches, a great cropper, and delicious in flavor.

The currant has the advantage of hanging on the bushes for several weeks, and is in order for the table for at least two months. One should have a few bushes of Prince Albert to lengthen out the season. Of course, if worms are allowed to defoliate the plants, the crop must be gathered very early and used for jelly, or it will sun-burn and sour.

The Crandall is not what it was sold for—a cross of native with foreign sorts. It is a pure native, somewhat improved. But it is half a humbug, after all. The bush lops about, and must be tied to stakes. The size of the currant is only that of a large fruit of the ornamental Missouri Currant grown in our shrubberies. The flavor is pleasant, but no improvement on that of the varieties grown for ornament. Let it be taken for what it is, and appreciated accordingly.

The propagation of the Currant is very easy. Take cuttings a foot length; set these into the soil in a dry place in October or November. Pack down the dirt very tightly and leave them until spring. Then a part will be found to have rooted, while the rest will have calloused and are ready for planting if you desire. In setting such small plants pack the earth very tightly about them. It is the secret of success.

The only enemy the Currant has generally is the well known worm that defoliates the plant. White hellebore dusted on will kill them. The best method of applying is to mix two tablespoonfuls of hellebore in a pail of water with one teaspoonful of kerosene. Riley's emulsion of kerosene is easily made and kept on hand. It is the best way of using it. I apply exactly the same mixture to Rose-slugs. Two generations of worms appear each season, and both must be killed. One of them hatches as the fruit is setting; the other as it is ripening. The hellebore should be applied the last time without kerosene, as it is sticky and helps dust to adhere to the fruit.

The Water Garden.

PERHAPS none of our wild flowers are more universally appreciated than the Water Lilies, and yet until one has cultivated Nymphæas and has had an opportunity to study them day by day their full beauty is scarcely appreciated; for this is a flower which appears at its best when daintily anchored in a clear pool. It cannot be too often said that in this climate all the Nymphæas and Nelumbiums can be successfully

grown in the open air without the aid of glass, and, with the exception of *Victoria regia*, no large estate is necessary, for room may be made in almost any small garden, if it is sunny, for a tank, which, with a little management, may be made a successful water garden.

Last year I noted in GARDEN AND FOREST (ii., page 405) an experiment in growing Nymphæas in sunken casks, which answered very well, but this season the natural result is a tank, which, while simply made and inexpensive, quite answers its purpose. An ordinary laborer dug an irregular pit about two feet deep, with slightly sloping sides, and after firming the bottom applied a coating of pure Portland cement, going over it twice, which made it water-tight. Even in light soils, I think a good coating of cement would answer without brick-work. It is well to apply this when the earth is dry, as otherwise cracks may appear in a very dry season. Of course, where permanence is desired, and the expense can be afforded, a tank with brick walls would be best. In as small a tank as mine (ten by twelve feet) it is requisite that there shall be an overflow and a convenient supply of fresh water, also that surface water shall not be allowed to flow into it. The water can be syphoned through the overflow if it be necessary at any time to draw it all off.

When first planted the large amount of manure used will somewhat foul the water, and there will be some rising of impurities, which should be floated out through the overflow; but the water will soon clear, and if the tank is well stocked with gold-fish, silver-fish or sun-fish, there should be no further trouble from impurities, mosquito-germs or algæ. Should it be desirable to hasten the settlement of any accidental turbidity, a spray of a very weak solution of alum would soon cause precipitation.

If the plants used are hardy and few it is as well to plant them out, but if rather numerous it will be more convenient to plant them in boxes or baskets. They are gross feeders and rank growers, and for a small tank it will be better to give only moderate root-room. Of course, one does not in this way secure the greatest development of foliage and flowers, but this is not essential to one's enjoyment always. If æsthetic considerations alone prevailed, a tank the size of mine would be well furnished with, say, two Nymphæas and a Nelumbium; but it is possible to grow a dozen varieties, and also find room for *Papyrus Antiquorum*, varieties of *Sagittaria*, *Alisma*, *Aponogeton distachyon*, *Eichornia crassipes*, *Limncharis Humboldtii*, etc., all of which are interesting and quite indispensable.

A flower-lover must feel in sympathy sometimes with M. Alphonse Karr's Tulip-amateur, who desired a chair that he might sit down and be alone with his favorite flower. No other spot in the garden so strongly suggests a similar longing as does the water garden. On its border in the morning of a summer's day one finds restful enjoyment in the beauty of the foliage, the varied bearing, form and coloring of the flowers, the fascinating water reflecting the changeful sky, the busy fish active as so many children, the frogs enjoying siestas on the Lily-pads—not nearly so sleepy as they seem—and the varied "small deer" which water attracts. And then the setting of the jewel! At one side, flanked by a Bamboo and *Spiræa*, are the flag-like leaves of Kämpfer's Iris, the graceful, quiet flowers being in tone with the surroundings; another side is filled with Cannas, Bamboo and Eulalias, with an undergrowth of Ferns, Primulas, etc. There a jutting point is made by a mass of peat, from which springs a colony of wildlings, and a Dwarf Sumach pendant over the water—a nice bit this. Convenient to the banks I find quiet places where small things, Saxifrages, Primulas, Droseras, etc., are at home in the moist air and the chance of a full supply of water. In an adjacent border I expect to establish an artificial bog connected with the tank, where can be grown many fine things which are troublesome or difficult in an ordinary garden. As will be seen, the accessories of a water-garden are scarcely second in interest to the garden itself, but some care should be used in selecting plants for such a position. The color-tone of the picture is low and quiet, and plants with bright, dazzling flowers should not be used, especially if dwarf-flowering. Cannas nowadays have dazzling flowers, but they are tall and too valuable otherwise to discard for their color. *Caladium esculentum* is also an excellent foliage plant in such a position, but in a small place the buildings give the winds a rotatory motion and the huge leaves are twisted off, so that it can only be grown well in open spaces. The larger Grasses are perhaps the best plants for such a position. Mr. Watson, in his notes from Kew a few weeks since, wrote of "the universal attraction of the aquatic tank," and nothing truer could be said; for it is a remarkable fact that the Lily-pond proves an attraction to every one, young or old, without exception—something which cannot be said of any

other class of plants, however showy or beautiful. Every grower who has been chastened by the average visitor, who, fearing "to be dilated with the wrong emotion," notices only the well known flowers and looks coldly on the unknown treasures, should provide a tank for a certain attraction.

"The King of Lilies."

I AM not aware that the great Himalayan Lily—*Lilium giganteum*—has been previously grown in the open air in this state; it is a stranger to western New York, I have reason to believe, until this season.

My first experience with this Lily dates back to the autumn of 1885, when several flowering bulbs were sent me from England. The gigantic conical bulbs were potted and housed in a cool house over winter and planted in the open in the spring, only to be cut down and killed by an unexpected sharp frost during early May. The following autumn a dozen small bulbs were sent me by a friend in North Wales. These, likewise, were potted and housed over winter, with the exception of three, which were planted late in November in the hardy fernery. The latter all put forth leaves the following spring, showing conclusively that the species is hardy in this climate. The remaining bulbs were also placed in the fernery and the shaded portion of the rock-garden. Of eight of the dozen bulbs which survived, four have just blossomed, the remaining four being strong plants which, unquestionably, will produce flower stalks next season.

The plants have all received a slight winter protection of leaves; and every spring the early projecting crown has been protected by pots or other covering whenever any danger from frost has appeared, this Lily being one of the very first plants to show above ground in spring and being extremely sensitive to sudden cold. The stem begins its ascent early in the season, throwing out the large heart-shaped leaves, which diminish in size as they advance upon the stem, the flowers forming in a great raceme at the extremity of the stalk. Even as a foliage plant, independent of its stately flower-stalk, this Lily, with its huge, glossy leaves, is strikingly attractive, and the leaves remain fresh and green until mid-autumn.

The strange beauty and majesty of the great Himalayan Lily must be seen, however, to be fully realized; and it is to direct the attention of all flower-lovers to one of the grandest of hardy plants that I am prompted to refer to it. Its beauty could only be fully portrayed by a poet. If any flower may be termed regal, this term applies to *Lilium giganteum*. It looks like the inhabitant of a tropical jungle—a sacred flower of the far east, supreme in its stateliness and its grace. Its suave, haunting odor sets me dreaming. Fragrances as of Jasmines, Japanese Honeysuckles and Gardenias; perfumes as of Cascarilla and Sandal-wood; spices as of Sassafras and Clove-Carnation cling to its long, chaste chalice and scent the entire garden in the evening. Then the cernuous poise of its great flower-cluster, nodding from the tall, tapering stalk above the majestic leaves, and the refinement and beauty of the long, trumpet-shaped blooms! A distinct feature of the six-petaled blossom is the penciling of the inner petals, these being exquisitely shaded with purple merging to deep lake, from the extremity of the flower to the flange of the chalice.

The height of the Bamboo-like stalk in the four specimens referred to varies from eight feet three inches to nine feet, the diameter of the thickest stalk exceeding two and a quarter inches. The flowers number from ten to twelve, while the individual blooms measure from eight to nine inches in length. After flowering, the stalk dies down and the old bulb shrivels and dies. Each bulb has thrown out from two to four offsets, which will be lifted and placed where desired in the autumn.

To obtain success with the "King of Lilies," it should have a sheltered and partially shaded position in rich garden soil and leaf mould, and receive abundance of moisture. An application or two of liquid manure will prove of benefit in developing the flowers. It is seen to advantage placed among the native red and yellow Meadow Lilies, which unfold their gay Turk's caps at the same period. A bed of *Lilium giganteum*, grown by themselves or with *L. auratum*, where the latter can be successfully grown, would be a novel and magnificent feature of any garden, more especially if placed against a background of green.

The last raceme of the last flowering plant now stands in a vase in the hall, and fills the entire house with its subtle, penetrating perfume, the odor being exhaled most intensely at night. The garden looks deserted since these giant Lilies have passed, and no blaze of the big Bee Larkspurs nor gay

rosettes of the ranks of the Hollyhocks serves to take their place. The "King of Lilies" is individual among hardy flowers.

Rochester, N. Y.

George H. Ellwanger.

Orchid Notes.

Catasetum atratum is an old but not very well known species, which has been in cultivation since 1838, when it was introduced from Brazil by Loddiges, of Hackney, with whom it appears to have flowered for the first time in cultivation. It is met with here and there in collections nowadays, and quite recently a splendid specimen of it was exhibited at a meeting of the Royal Horticultural Society, as a proof of what a handsome plant it might be made by good cultivation. Fully developed pseudo-bulbs are from nine to twelve inches long, oblong-conical in shape and covered with silvery ribbed sheaths. The young pseudo-bulbs are green, and bear at the summit from four to six broadly-lanceolate deep green leaves twelve to sixteen inches long, which are traversed lengthwise by three conspicuous ribs or veins, and are more or less plaited. The stout glaucous-green, arching scape springs from the base of the young pseudo-bulb and reaches a length of two feet or more, the upper half being furnished with as many as thirty flowers, each of which is about two and a half or three inches across, if fully extended. The sepals and petals are broadly lanceolate-acute, deep green, and thickly covered with blackish purple spots, which are much more numerous on the sepals than on the petals. The thick, fleshy lip is ovate-acute when spread out, sharply recurved at the apex, and having a deep cavity at the base, the sides of which are colored green, with blackish purple spots, while the anterior portion becomes pale creamy yellow. The margin is furnished with a jagged, bristle-like fringe, which is longer and stiffer at the base. The column is green, speckled on each side at the base with purple-brown, and having two pale horns or antennæ passing from the sides in front into the cup of the lip.

C. atratum is apparently an easy species to grow, requiring the same treatment as others of the genus. Pots or baskets, with a compost of rough peat and sphagnum, placed over clean crocks, are equally suitable receptacles for it. When the new growth makes its appearance then watering must be regularly attended to, and the frequency of the supplies should be increased according to the rapidity of growth. A tolerably warm and moist house, which can be well ventilated without causing draughts, is well adapted for growing purposes, and although direct sunlight on the plants cannot be recommended with safety for more than a short time in the morning, nevertheless as lightsome a position as possible will be found best for ripening the growths, thus enabling them to store up abundant material for the resting period during the winter months.

London.

John Weathers.

Odontoglossum Schliperianum.—This is one of the most useful and at the same time prettiest of this large genus now in flower, and it deserves special mention, as the present is a very dull time of year for *Odontoglossums*, and, in fact, for any Orchids. *O. Schliperianum* belongs to the section containing *O. grande* and *O. Insleyi*, and it is difficult to distinguish one from the other when not in flower. *O. Schliperianum* produces its flowers on stout spikes from fifteen to thirty inches in length, and bears from five to fifteen or sometimes more flowers, which are about three inches in diameter. The sepals and petals are bright golden yellow, barred on the basal half with bright chestnut-brown; the lip is lighter in color and barred with lighter bands; the apical half of the sepals and petals are clear yellow, making a flower very much admired.

If flowering with *O. grande* this species might easily be taken for a smaller form of the latter, so much alike are they.

O. Schliperianum should be grown on the side-benches of the Cattleya-house, where it will be close to the glass and receive a good amount of sun and air. In watering, care must be taken not to wet the foliage, as this causes the objectionable black spots so often seen on the three species named above. Water given about once a week will amply suffice while the plants are growing, and it should be withheld almost entirely after growth is completed, in which respect they differ from most of the other cool *Odontoglossums*.

Easton, Pa.

Henry Clinkaberry.

Rose Gloire de Dijon.—With this I send you a few sprays of the old *Gloire de Dijon* Rose to show what fine buds one can have from this favorite plant all the season. The first flush of bloom in June is so abundant that unless the plants are well cared for and in very good soil many buds fail to develop fully.

But after the first bloom the plants rapidly make new growth, and one can usually find a few good buds at any time during the summer. October frosts only put a stop to their flowering. I have four plants with a southern exposure, which have been established some three or four years, and though somewhat neglected, they prove perfectly satisfactory low climbers. In winter a Russia mat is tacked over each plant, and so far they have proved as hardy as the ordinary Hybrid Perpetuals.

Elizabeth, N. J.

G.

[The buds are of good size and substance, and from their position at the extremity of the strong shoots they can be cut with long stems, which are furnished with the best of foliage.—Ed.]

The Forest.

Notes on the Ligneous Vegetation of the Sierra Madre de Nuevo Leon.—II.

AS I begin now to give an account of the forests of the Sierra Madre south of Monterey and of the trees which compose them, I am embarrassed by the conviction that the months spent in exploring that region were quite inadequate to the acquiring of all the facts concerning the species growing on the almost inaccessible steeps of those fearful mountains, or locked up in their interior fastnesses. I can do no more than to communicate what I learned there.

The usually abundant precipitation of rain upon the eastern slopes of this mountain chain ensures their being covered with a forest-growth whose size and density are in direct ratio to the amount of soil covering them. True, the depth of soil is slight, when compared with that covering our northern mountains, where glaciers have wrought in the ice age, and where frost still works to the same end; yet here, somehow, there is maintained a constant verdure, the sight of which is refreshing to eyes which have long rested on the eternal grays and browns of the bare mountains of the northern table-land.

On these fresh slopes and on the broader of the mountain tops *Pinus Montezumæ* finds its northern limit of distribution. It is a valuable tree, eighteen to twenty-four inches in diameter and forty to fifty feet high, and fills in this region the place held by *Pinus ponderosa* in the forests of New Mexico and Arizona. Its cones were seen to be extremely variable, the smaller being ovoid in shape and barely two and a half inches long, the larger oblong and fully six inches.

Beginning at a somewhat lower elevation, about 2,500 feet, but mingling with this species in about equal proportion and of no less size, was found another Pine ("Pl. Mex.," No. 1964), which has not yet been referred to any known species. These two Pines were seen to form some really fine belts of timber.

Of especial interest were belts of *Carya myristicæformis*, covering, largely to the exclusion of other species, certain rocky slopes. In the scantier soil this species makes but a scrubby growth, often no more than a shrub; but in moist and rich cañons it becomes a good-sized tree twelve to eighteen inches in diameter.

Carya olivæformis seemed to be restricted to wet cañons and springy places, and to attain to larger dimensions than the preceding.

The lower slopes of these mountains abound in wet cañons, and these are occupied by a dense growth of the following species: *Juglans rupestris* (doubtless this species, though the green nuts were three inches in diameter); *Quercus polymorpha*, attaining a size of two feet by sixty; *Quercus virens*, its maximum diameter three to five feet; *Platanus Mexicana*, a large tree and widely branching; *Fraxinus viridis*, var. *Berlandieri*, perhaps the largest of American Ashes; *Morus urticæfolia*, a small tree; *Tilia Mexicana*, eighteen to twenty-four inches in diameter and forty or fifty feet in height; *Chilopsis saligna*, amid tall trees itself tall but slender; *Ulmus crassifolia*, not large, as on river bottoms; *Planera aquatica*; *Bumelia lanuginosa*, var. *rigida*, six

to eight inches by fifteen to twenty feet; a variety of *Prunus Americana*, *Prunus Capuli*, the largest specimen seen being eighteen inches in diameter and forty to fifty feet high; *Cercis reniformis*, sometimes attaining to a diameter of one foot and a height of forty; *Leucæna pulverulenta*, *Cornus florida*, one foot by twenty-five, and *Staphylea Mexicana*, n. sp., six or eight inches by fifteen or twenty feet.

Several of the above list are found scattered in specimens of inferior size outside of the cañons. There they mingle with *Quercus Grahami*, a small tree most abundant from the lower to the higher slopes, whose bark supplies the tanneries of the region; *Q. oblongifolia*, not common here, and another species of *Quercus* as yet undetermined, and *Arbutus Texana*, from six to twelve inches in diameter, usually with low heads, with grotesque trunk and branches covered with smooth, white bark.

On the precipitous ledges of lime rock—even arising from the fissures of the great cañon walls or waving their leaves from the sharp mountain crests—are seen numerous specimens of the upland Palmetto, *Brahea dulcis*. In so dry and poor situations the plant seldom exceeds a height of twenty feet; but far to the south in low valleys of the south-eastern part of the state of San Luis Potosí, I have seen it rising to forty or fifty feet and forming close forests.

About the base of the mountains, especially on limestone ledges, associated with *Fraxinus Greggii* and *Heliella parvifolia*, which sometimes acquire the size and habit of small trees, and *Diospyros Texana*, here rather shrubby, we find *Amyris Madrensis*, n. sp., the largest specimens of which met with were seven inches by twenty-five feet, and *Sargentia Greggii*, n. gen., one foot by twenty-five. The foliage of these two is evergreen; and *Sargentia*, with its large, shining leaves, and yellow, oval fruits an inch long, is an interesting plant. Except in the richer gulches it usually appears here near its northern limit of distribution as a large shrub; but as far south as the state of Vera Cruz and at but slight elevation above the sea I have seen it common in tropical forests as a tall, slender-stemmed tree.

Common in rich valleys among the foot-hills we find *Acacia Farnesiana* and *Acacia flexicaulis*, the former one foot in diameter and the latter one and a half to three feet, both low-branching, round-headed trees. *Ehretia elliptica*, more erect in habit and one to three feet through; *Condalia cuneata*, tree-like in habit, but a very small tree; *Pithecolobium brevifolium*, and occasional specimens of *Sapindus acuminatus*.

The principal shrubs or woody vines noticed in the Sierra Madre are: *Cocculus diversifolius*; *Berberis gracilis*, in broad clumps ten feet high; *Berberis trifoliolata*, a smaller plant; *Fouquieria splendens*, not abundant here in its eastern limit; *Decalopis Coulteri*, five to fifteen feet high, slender, and with but few branches, very abundant on limestone ledges and seen in similar situations in south-eastern San Luis Potosí, but appearing less common; *Karwinskia Humboldtiana*, here two or three feet high and spreading by its roots in wide clumps, but found in Jalisco twenty feet high and with single stems; *Hiræa macroptera*, extensively trailing over walls, shrubs, etc., and bright during many weeks of summer with profuse yellow flowers; *Hiræa lilacina*, rather rare; *Xanthoxylum Fagara*, fifteen or twenty feet high, often forming thickets, not noticed here, with single stems; *Rhamnus*, sp., seen here as a tall shrub, but in Chihuahua as a small tree; *Coludina Greggii*, reaching twenty feet in height; *Ceanothus azureus*, slender, ten feet; *Ampelopsis quinquefolia*, common and higher on the mountains, its variety *pubescens* of Gray (*A. pubescens*); *Ungradiad speciosa*; *Dodonea viscosa*; *Rhus virens*, a large stout shrub, sometimes almost a tree, a handsome evergreen with panicles of pink flowers or scarlet fruits; *Rhus Toxicodendron*; *Rhus Mexicana* (*Pistacia Mexicana*), observed six or eight inches in diameter and twenty or more feet high, but always with the habit of a shrub, branching at the ground and spreading; *Eysenhardtia amorphioides*, five to fifteen feet high; *Dalea frutescens*, var., a slender

shrub, six to ten feet high; *Dalea Domingensis*, two or three feet high; *Sophora secundiflora*, about fifteen feet; *Bauhinia lunarioides*, fifteen or twenty feet high; *Mimosa malacophylla*, a horribly hook-spined vine, widely climbing over shrubs; *Rubus trivialis*; *Cotoneaster denticulata*, eight to twelve feet high, with somewhat virgate stems; *Rosa Mexicana*, low and slender, on cool grassy slopes, under Oaks and Pines; *Philadelphus Coulteri*, on cliffs and ledges; *Nesaea salicifolia*, common along streams; *Garrya ovata*, var., *Abelia coriacea*, on summit ledges; *Randia Xalapinsis*, an erect shrub, ten to twenty feet high; *Chiococca phenostemon*, with wide, shining evergreen leaves, and panicles of white flowers or white fruits, very ornamental, so large and stout a shrub that I expect yet to find it as a tree; *Wyethia Mexicana*, n. sp., a composite shrub three to six feet high; *Forestiera racemosa*, n. sp., stems two to six inches thick, and ten to twenty feet high in clumps; *Buddleia Humboldtiana*, extremely variable in size and character; *Brachistus Pringlii*, n. sp., here about three feet high, further south ten; *Lantana Camara*; *Lippia lycioides*; *Lippia macrostachya*, six to ten feet; *Berendtia spinulosa*, n. sp., rooting from fissures of the driest limestone cliffs and spreading over their faces; *Croton fruticulosus*, here a fall shrub; *Bernardia myricæfolia*; and *Stillingia sanguinolenta*, some six feet high, in large clumps by streams.

Periodical Literature.

The Blue Grass region of Kentucky is charmingly described by John Burroughs in the *Century Magazine* for July, under the title, "A Taste of Kentucky Blue Grass." It is in truth a taste he gives us—more than a mere glimpse; the soul of the landscape as well as its body has appealed to him, and he transports us for a moment into its generous open spaces and gives us the flavor of its cool winds and luscious vegetation. As he says, the man of the woods and the man of the fields both reside within him, it was, of course, to the latter that this region spoke so attractively. Charming indeed is an opening passage: "A perfect issue of Grass or Grain is a satisfaction to look upon, because it is a success. These things have the beauty of an end exactly fulfilled, the beauty of perfect fitness and proportion. The barren in nature is ugly and repels us, unless it be on such a scale and convey such a suggestion of power as to awaken the emotion of the sublime. What can be less inviting than a neglected and exhausted Virginia farm, the thin red soil showing here and there through the ragged and scanty turf? and what, on the other hand, can please the eye of a countryman more than the unbroken verdancy and fertility of a Kentucky Blue Grass farm? . . . One likes to see the earth's surface lifted up and undulating a little, as if it heaved and swelled with emotion; it suggests more life, and at the same time that the sense of repose is greater. There is no repose in a prairie; it is stagnation, it is a dead level. Those immense stretches of flat land pain the eye, as if all life and expression had gone from the face of the earth. There is just unevenness enough in the Blue Grass region to give mobility and variety to the landscape. From almost any given point one commands broad and extensive views—immense fields of Wheat or Barley, or Corn or Hemp, or Grass or Clover, or of woodland pastures. . . . The Blue Grass region is as large as the state of Massachusetts, and is, on the whole, the finest bit of the earth's surface, with the exception of parts of England, I have yet seen. In one way it is more pleasing than anything one sees in England, on account of the greater sense of freedom and roominess which it gives one. Everything is on a large, generous scale. The fields are not so cut up, nor the roadways so narrow, nor the fences so prohibitory. Indeed, the distinguishing feature of this country is its breadth: one sees fields of Corn or Wheat or Clover of from fifty to one hundred acres each. But the feature of this part of Kentucky which struck me the most forcibly, and which is perhaps the most unique, are the immense sylvan or woodland pastures. The forests are simply vast grassy orchards of Maple and Oak, or other trees, where the herds graze and repose. They everywhere give a look to the land as of royal parks and commons. They are as clean as a meadow and as inviting as long, grassy vistas and circles of cool shade can make them. All the saplings and bushy undergrowths common to forests have been removed, leaving only the large trees scattered here and there, which seem to protect rather than

occupy the ground. Such a look of leisure, of freedom, of amplitude, as these forest-groves give to the landscape!

"What vistas, what aisles, what retreats, what depths of sunshine and shadow! The grass is as uniform as a carpet and grows quite up to the boles of the trees. One peculiarity of the Blue Grass is that it takes complete possession of the soil; it suffers no rival; it is as uniform as a fall of snow. . . . Sometimes the more open of these forest lands are tilled; I saw fine crops of hemp growing on them, and in one or two cases corn. But where the land has never been under cultivation it is remarkably smooth—one can drive with a buggy with perfect ease and freedom anywhere through these woods. The ground is as smooth as if it had been rolled."

The fertility of this region may well seem marvelous to the dwellers on New England farms—a fertility, as Mr. Burroughs explains, which is due to the old limestone rock "laid down in the ancient Silurian seas. The earth's surface seems once to have bulged up here like a great bubble, and then to have been planed or ground off by the elements. This wearing away process removed all the more recent formations, the coal beds and the conglomerate or other rocks beneath them, and left this ancient limestone exposed. Its continued decay keeps up the fertility of the soil. Wheat and Corn and Clover are rotated for fifty years upon the same fields without manure, and without any falling off in their productiveness. Where the soil is removed the rock presents that rough, honeycombed appearance which surfaces do that have been worm-eaten instead of worn. The tooth which has gnawed, and is still gnawing it, is the carbonic acid carried into the earth by rain-water. Hence, unlike the prairies of the west, the fertility of this soil perpetually renews itself. The Blue Grass seems native to this region; any field left to itself will presently be covered with Blue Grass. It is not cut for hay, but is for grazing alone. Fields which have been protected during the fall yield good pasturage even in winter. And a Kentucky winter is no light affair, the mercury often falling fifteen or twenty degrees below zero."

Correspondence.

A Troublesome Grass.

To the Editor of GARDEN AND FOREST:

Sir.—I enclose a sample of coarse Grass which is infesting my lawn. Will you kindly tell me what it is, and how I shall proceed to get rid of it? It has been making a vigorous growth all through June, and although the Blue Grass on the lawn is cut closely every week, this jointed intruder snakes along under it and throws out shoots a yard in length which root at every joint. It seems indestructible, unharmed by the sun of July or the frosts of winter. Is there any hope for my lawn?

Frankfort, Ky.

Mrs. W. T. S.

[This letter gives a forcible description of some of the bad qualities of the Bermuda Grass (*Cynodon Dactylon*) and the accompanying specimens prove that this is the pest.

Bermuda Grass, sometimes called Wire or Scutch Grass, is a strange combination of the good and bad. In the northern states it is a dwarfed, late-starting grass of no value for forage, and may become one of the worst of weeds, requiring the utmost vigilance to subdue it. In the south it is highly prized for pasturage, as it thrives upon sandy soil under a tropical sun, forming a stiff turf that binds securely the loose earth upon which it grows. Professor Beal, in his work on "Grasses of North America," quotes from Professor Phares, an expert student of southern grasses, as follows: "As a permanent pasture grass I know no other that I consider so valuable as this." Howard says that it is doubtful whether any crop is more valuable in the south than the Bermuda Grass when grown at its best. When we leave the south and reach as far north as Kansas, for example, it has been determined by careful experimentation that this grass is worthless for either pasture or meadow—it is only a weed of the most pernicious sort. When looked at from the weed-standpoint, as it must be in the belt of states between the north and south, it is encouraging to know that it rarely seeds in the United States; but like some other species of plants that rarely mature fruit, the Bermuda Grass has a remarkable way of spreading by its root-stocks, in which tendency it resembles our own Quack Grass. To eradicate the pest from a

Blue Grass lawn there seems to be no other way but to clean the land by digging out and destroying every root and root-stock so far as possible, and then to watch carefully for its second coming and attack it again at its earliest appearance.—Ed.]

Notes.

It is believed that the Hollyhock was brought to Europe from China as early as the year 1573.

About 1,400 species of Orchids, 1,100 of Ferns and 500 of Palms and Cycads are grown in the Botanic Gardens at Kew.

An edition of Mr. George H. Ellwanger's "The Garden's Story" has been published in England with a pleasant preface by C. Wooley Dod.

According to a letter recently published in the *Popular Science Monthly* the finest hand-spun Belgian flax, such as is used in making costly lace, is worth from \$900 to \$1,000 a ton.

Mr. James H. Laing, of the Messrs. John Laing & Sons, the well known nurserymen, florists and specialists in Begonias, of Forest Hill, London, has sailed for New York on a tour through the United States.

A writer in *The Argosy*, Demerara, says that the blue spikes of the pretty pond-weed, *Eichornia tricolor*, from Brazil, are excellent for cutting. The little flowers fade at evening, but a new crop opens next morning, so that a spike will continue to bloom for more than a week until all its buds are exhausted.

Writing in *Zoe*, Mr. F. H. Vaslit notes the following plants as having escaped from cultivation and become naturalized in the Coast Range Mountains: Garden Chrysanthemums, which seem to be becoming true "weeds," that is, are already "rather troublesome to get rid of"; Fuller's Teazle (*Dipsacus Fullonum*); Mourning Bride (*Scabiosa atropurpurea*); and the larger Periwinkle (*Vinca major*).

The English horticultural journals continue to lament the prevalence of the Lily disease among the Ascension Lilies. In some places not a single flower bloomed this year from a hundred bulbs. This disease has been very deadly in this country and is so still in many places, but near New York this year it seems to have abated and the Lilies in many gardens have proved unusually strong and beautiful.

It is said that since the opening of navigation on the Caspian Sea this spring more cotton has been brought from central Asia to Moscow than during the whole of the year 1889. Experiments are now being made with the Cotton-plant in the Crimean peninsula and in other places along the coast of the Black Sea with seed brought partly from more eastern regions and partly from America.

It is only in very recent years that the name Gardenia has been commonly applied in this country to the handsome flowers for which it is the correct botanical name as well as the one almost invariably used in England. Here they have been most generally called Cape Jessamines, although they come from China and are not botanically Jasminums. Yet the genus was named for Dr. Alexander Garden, of Charleston, South Carolina, who was a valued correspondent of Linnæus.

Limnanthemum Indicum, just now blooming, lifts its white, star-shaped flowers, which are about as large as a five-cent piece, only an inch or two above the water. The inside of the petals—that is, their upper side when opened—is covered with fine filaments which stand as thickly as those on the Mrs. Hardy Chrysanthemum, and these give the flower such a light and feathery look that the name "Water Snowflake" would suit it well. It has floating foliage like that of a miniature *Nymphæa*.

Mr. William W. Lunt, of Hingham, Massachusetts, has sent to this office for inspection a sketch in colors of a remarkably fine variety of *Cypripedium* (*Selenipedium*) *caudatum giganteum* which differs from the type in that the prevailing color is a reddish or bronze-like brown and yellow, instead of dark brown and greenish. The pouch is also more nearly globular, but the striking feature of the plant is its high-colored staminate and the great size of the lower sepal. The entire flower is large. The plant is in a four-inch pot, and has three old growths and three breaks.

The yellow Water Lily which originated with Monsieur Marliac in France and which was named by him *Nymphæa Marliacea chromatella* has proved quite hardy in Bordentown, New Jersey, where it remained all winter in a basin eighteen

inches deep on the grounds of Mr. Sturtevant. It is now blooming in several places near this city and it is one of the handsomest of aquatic plants. It is a trifle larger than *Nymphæa odorata*, fragrant, with lemon-yellow petals and orange stamens which intensify the apparent richness of its color. Its foliage resembles that of *N. candidissima* and it flowers continuously from early summer until frost.

A correspondent of the *Gardeners' Chronicle* gives the following as a select list of the finest varieties of Laced Pinks: they are Beauty, a small flower, but very free to cut from; Bayard, a large and full flower, beautifully laced with bright red, a grand variety that laces well, and probably the best Pink in cultivation; Clara, smooth, fine, a beautiful petal, regularly laced with reddish purple; Empress of India, a very distinct variety with rich deep lacing, extra fine; Eurydice and Excelsior, very good; Device, George White, Harry Hooper, rich dark lacing; Jessica, Minerva, and Modesty, a very early variety, with bright rosy purple lacing; Mrs. Waite, small, but very pretty and free, and a charming border variety; and Rosy Morn, a very handsome Pink, with broad lacing.

A correspondent inquires how Professor Smith uses an umbrella with a sack attachment to gather in Rose-chafers. The collecting umbrella had better be specially made. Over an old frame stretch a cover of oiled-silk or linen, and cut out the crown, so that when the umbrella is open there will be a round hole, about six inches in diameter, in the centre. To this opening is sewed a bag about eighteen inches in length, open both ends, but so arranged that the bottom can be drawn together by a string. This bag, which will hang from the bottom of the umbrella when inverted, should also be of oiled-silk or linen, so as not to give the beetles a foothold. To any rough material the insects will cling so closely that they must be picked off to be dislodged, and from a cheese-cloth bag, such as Professor Smith first tried, the beetles crawled for hours afterward. To a smooth surface they cannot cling, and by loosening the string at the bottom of the bag the whole contents can be readily dumped.

In one of his pleasant articles in *The Garden*, a "Gloucestershire Parson" writes with feeling of the ravages among rare plants by collectors: "It is sad to see the depredations which are made upon some of our rarer seaside plants. I have seen ladies—'towrists,' as the villagers generally call them—go down with baskets, trowels and small steps into the beautiful sea caves to carry off from thence huge specimens of *Asplenium marinum*. Now nothing adapts itself so well to culture in a warm house as this *Asplenium*. It rapidly makes a lovely specimen with its dark green, glossy fronds. But to rob the dripping caves of all their beauty in such a way is really too selfish. Moreover, small specimens always grow better than large ones, so that it is a mistake for the depredators to trouble and burden themselves with baskets and implements and large plants. I believe I still know of caves, as yet untouched by the tourist depredator, where this Fern luxuriates, and spreads its dark green leaves in the shadow of the rock to the soft sea breeze. But ere long every place will be found out."

Dr. Harris, in a paper read before the Pennsylvania Horticultural Society recently, called attention to the fact that some of the most valuable vegetable productions, like the White Potato, the Tomato and the Egg-plant, are the results of development in a family which produces the Tobacco, the Jamestown Weed and the deadly Nightshade; and still more singular is it that edible innocence in a product may be intimately associated with a poisonous element in the plant. Starch-yielding tubers may even be in themselves an association of simplicity and venom, as we find in the Cassava, from which tapioca is obtained, the soluble elements of the tuber being poisonous, and the insoluble starch and pulp edible. In the White Potato we have a *Solanum* which has poisonous sprouts and fruit, with a valuable and innocent tuber or subterranean root-stock. The poison, solania, is found in the white sprouts of the tuber and in the green seed-ball or fruit, but not in the tuber as prepared for the table by boiling or roasting. Solania is not a powerful poison, and is one of very uncertain strength; still, death has been produced in childhood by eating the balls. Very young tubers and old sprouted ones are unwholesome food, for these contain a fraction of the poison. The Tomato plant contains solania, while the fruit, which has the same unpleasant odor, is free from it. Three deadly poisons, among the most potent of all active vegetable principles, are obtained from some of the *Solanaceæ*—namely, nicotia, from Tobacco; daturia, from Stramonium, and atropia, from Belladonna. One drop of pure nicotia will kill a large dog in a few minutes, and the other two are fatal in minute quantities.

Protection for the Originators of New Plants.

HOW the originators or introducers of new varieties of plants can be protected in what seems to be clearly their right to some special proprietorship of their productions is a subject that has often been discussed. At the late Convention of Nurserymen in this city the fact was emphasized that very few persons in this country who had originated valuable varieties of fruit had received any direct benefit from it. As an illustration it was stated that Mr. Worden, who brought out the Grape named after him, and which many people esteem, all things considered, as the best black Grape grown, is now a poor man, and never made \$500 from this valuable introduction. If inventors are protected by law against the piracy of ideas which have cost them labor and study, it would seem just that a man should be able to reap some reward for having brought out after much thought and experiment a new fruit which may add to the wealth and comfort of millions.

Different plans for patenting plants have been often advocated, but the essential objection to them all was well stated by Professor Bailey more than a year ago in this journal (ii., 1888), as follows: "It is exceedingly doubtful if a patent could be secured for varieties which spring up from a chance seedling, and most of our varieties come in this way. But if the patent were granted there are innumerable cases in which no jury of experts could agree concerning the distinctness of varieties." Few cautious persons would be willing to swear to the identity of a given Strawberry or Rose, and it would be difficult to prove in any given instance that the flower or fruit in question was not a new one closely resembling an older variety.

In an earlier number, vol. ii., p. 46, Mr. A. L. Bancroft, of California, suggested a horticultural register wherein separate plants like Roses, Chrysanthemums, Ferns, Apples, Grapes, could be kept and numbered, on a system similar to that adopted in the various herd-books where choice live stock is registered, but we then pointed out that a herd-book was devised for a purpose quite distinct from those which it is proposed to secure by a system of plant registration. Individual animals are registered so that they may be identified, that their pedigree may be estab-

lished and that purity of blood may be maintained in a given breed or strain of live stock. In the case of plants, where the registration of one individual must stand for an entire class and where the parentage is often unknown and always of secondary importance, it is difficult to see how such a list would prevent a duplication of names for the same plant or the selling of different plants under the same name. Mr. Bancroft's scheme has been carefully elaborated since then, and a plan of registration has been adopted by the California State Horticultural Society. We have no space here to go into the details of the plan, which have been very carefully elaborated, but as it was discussed it seemed to the nurserymen in their convention that it was quite too cumbersome to be practical and effective.

There is, however, considerable protection already given to the originator of a new fruit in the copyright law. Mr. Hoyt, of New Canaan, Connecticut, stated that he had taken out such a right on his label of the Green Mountain Grape and had been instructed by eminent legal authority that no man could use this title on a label to a Grape vine and sell it without his consent. It is true that if any one should buy a plant of Mr. Hoyt he could propagate it as largely as he chose for his own use, or could sell the vines under another name, but there would be little temptation to a grower to sell a really valuable variety under a name which would conceal its identity. The name is the very thing the plant-pirate most wants, and he very often sells nothing else but the name of a good variety, attaching it to an entirely different plant from the one it really belongs to. This registered trade-mark has proved of value too in preventing the sale of spurious plants under the label so registered, so that copyrighting assists in preventing the sale by unauthorized persons both of genuine plants and their counterfeits.

It is hard to see how much greater protection than this can be secured by a horticultural register. The plan of registering new plants has, however, many merits in other directions. It would be of interest to have an accurate description of any new plant filed in some public office, with its portrait and parentage so far as known. We should like to compare a plant and berry of Hovey's Seedling Strawberry as grown to-day with a preserved specimen of the original plant and its berry, or accurate portraits and descriptions of them, to see if any variation from the type had taken place. In questions of identity the register might give some assistance, but the inherent difficulties of accurate varietal description would remain. An organized effort to secure registration would be of value, too, in enlisting the co-operation of all horticulturists to secure to originators their rights, for, although no system yet devised can add much to the protection now given by the trade-mark laws, this protection would be much more effective if it had an active and united public sentiment behind it.

Of course this protection to the introducers of new plants would make such plants more expensive for a time, just as patented machinery and copyrighted literature is more expensive. But although this increased price might be considered a burden upon horticulture the advantages gained would be positive and important. Chief among these would be the encouragement offered to careful experiments in hybridizing. When growers can feel sure that they will reap some reward from discoveries in this field, we may entertain a reasonable hope that the breeding of plants may be reduced to something like a system or a science.

It is well known that several of the groves of the Giant Sequoia in the California Mountains have been invaded by the axe and that lumber from many of the Big Trees has gone into the market as Redwood. Most of the timberlands in which the Sequoia occurs have passed into the hands of lumbermen and speculators; but according to the *Visalia Delta*, one grove of these grand trees still remains in Tulare County in the hands of the Government. An enthusiastic description of the tract is given, but this was brought out by the fact that surveyors and locators are

now exploring the land and preparing to pounce upon it in the expectation that it is about to be opened for entry.

It seems that five years ago several townships in this county were withdrawn from entry, on account of alleged fraudulent practices, and it has been understood that they would not be restored until after official examination into the character of the surveys. It was believed, therefore, that if the Department changed its decision ample public notice would be given. It has turned out, however, that some of the Sequoia lands have been suddenly restored, and were at once secured by speculators and lumbermen, who seemed to have been prepared for the occasion by some private notification. The presence of locators in the tract mentioned naturally arouses the suspicion that the last remaining grove is doomed to the fate of all the others.

May we not hope that Secretary Noble will interpose to prevent such a disaster? Surely the Government should hesitate before surrendering to destruction this last cluster of these world-famous trees. If it ever is a duty of civilized society to preserve for posterity objects of natural beauty or grandeur, nothing more worthy of such protection than these giant trees can be named. They ought to remain the property of the nation forever.

The Gardens of the Fountain at Nîmes.*

FEW gardens in Europe equal in beauty those at Nîmes, which the people call simply *La Fontaine*, considering, it seems, the rest of the enclosure a mere appanage of the fountain itself. Few gardens, even in Italy, have greater historic interest, and none in any land surpass them in individuality or in the happy combination of formal and natural elements. Their earliest features date from before the time of Christ; their latest were created in our own century. Yet all now blend in an enchanting harmony of happily managed contrasts.

The so-called fountain is really a great spring filling a basin seventy-five feet in diameter and twenty-five feet in depth, in the natural rock on a steep hill-side, and fed from natural underground reservoirs, some of which are so distant that the waters will suddenly surge up in it at times when no rain has fallen at Nîmes. To its existence was due the existence of the city. Around it in Celtic times grew up a small town called Nemoz, whose inhabitants naturally held its plenteous waters sacred. Under Roman rule and the Latinized name of Nemausus this grew to a place of first importance. The fountain was nearer the centre of the Roman than of the modern city, and was utilized in baths which necessitated a group of beautiful buildings, some relics of which still survive.

The baths proper and most of the accessory structures were probably destroyed in the invasion of the Visigoths in the fifth century; and they or the quick-succeeding Franks broke the dikes which had regulated the flow of the waters and caused them to seek a new channel down the hill-side. But the sacred edifice (its ruins are now popularly called the Temple of Diana), which stood against the hill-side, not far from the spring, was saved and became the church of a house of nuns upon which, in 991, the fountain and the adjacent lands had been bestowed. It was called the *Abbaye de St.-Sauveur-de-la-Font*, and many were the disputes between its inmates and the townsfolk, as the centuries rolled by, over the possession of the spring and of the mills turned by its escaping waters, as well as over the right to use certain meadows adjoining the canal as a place of public promenade.

A settlement was made in favor of the town in 1352, but disputes still went on with regard to the rights of the nuns over the fountain itself and the canal, until the monastery was razed, in 1563, the nuns were dispersed, and, in the religious conflicts of the following year, it was reduced to the ruinous, but picturesque, state in which we now see it.

For generations after, the spring was constantly discussed, with a view to increasing and regulating its flow, and thus preventing that almost total drying up which, in late summer, brought the local industries to a stand-still. Trees were planted, and there was much digging among the old baths, but little was accomplished until 1744, when Jacques Philippe Maréchal, Director of Fortifications for the Province of Lan-

guedoc, presented a plan which was accepted, and associated with himself in its execution an architect of Nîmes named Dardailhon, whose scheme had seemed to him the best of the preceding ones. The work was at once begun, and was finished in nine years at a cost of about 1,000,000 francs.

Let us see now how the gardens look to-day. The main approach is through a wide boulevard, planted with double rows of trees on either side, which brings us to the great iron gates seen in the distance in our picture (see page 371). Hence to right and left the eye follows broad tree-bordered canals, widening into many-angled basins at the two corners of the garden, and thence to the right, leading the waters of the distant spring down a wide shady street, which really deserves the name of *Quai de la Fontaine*. Entering the gates we are in a large rectangular space, through which run quadruple lines of ancient trees, leading the eye to the bath as the central feature of the garden. Other avenues surround the space; beyond them runs the canal and still more avenues. The canal is broken in its circuit of this space only by the entrance path at the gateway, and opposite by two bridge-like paths between which it is continued as a square basin. The avenue-trees are chiefly Lindens and Horse-chestnuts. As we follow the bridge-like paths, we see in front of us—in the centre of a wide expanse of gravel still planted with shady avenues—the modernized remains of the baths, which our illustration shows from the opposite point of view. They consist simply of a great square, sunken and flooded basin, surrounded by a colonnade, behind which lie small rooms or cells, and in the centre of which rises an island, where many changes were made, notably those in the centre of the picture, where the angle vases and centre group take the place of interesting Roman relics. Of course, all the balustrades and other vases, which add so much to the beauty of the arrangement, are works of Maréchal's time. Indeed, the whole thing is so distinctly Rococo in its general effect and in almost all its details that it is hard to believe any part of it antedates the age of Louis Quinze. The island is a mass of blossoming shrubs, largely broad-leaved evergreens, amid which, in late July, great sprays of Pink Oleander were blazing—all forming the most effective of backgrounds for the graceful, if somewhat affected, work of the Rococo sculptor.

The art with which the vicinity of the basin is treated will be clearly appreciated from the picture and the fine contrasts of the snowy balustrades with the thick masses of foliage. The canal in the foreground leads diagonally for a short distance to the spring, whose great basin is bordered in a similar way so that its natural character is scarcely apparent. But all this is only a small part of the garden. To the left, if we stand as in the picture, behind the trees in the middle distance, is a broad triangular graveled space, thickly shaded by rows of Lindens, Horse-chestnuts and Planes, with Orange-trees between them in boxes gayly striped with yellow and green. Closer at hand the hill-sides rise all around us; they are low on our right, sheltering the Temple of Diana near the spring; on our left, beyond a broad open space and a strip of lawn, they rise almost perpendicularly as a wall of rock about fifty feet in height; and behind us they are again as high, and are backed in their turn by the steep and lofty hill called Mont Cavalier, on whose summit stands the ancient Tour Magne.

Here we begin to see how nature has been blended with art in this garden. The hill near the temple is covered with a seemingly natural growth of trees, chiefly Pines. Opposite, the perpendicular rock is clothed with the richest masses of free-growing vines and creepers. Great spiky Agaves and stiff Palms grow from the crevices and ledges through the mats of swaying foliage, making a delightful picture. Nothing could be finer than this cliff as a back for the diagonal perspective of avenues and balustrades, if the little lawn at its foot were not disfigured by an ugly statue of a local poet and by formal flower-beds of garish hue, perhaps the only note of bad taste to be found in the whole garden.

It would not have been well, however, to continue the naturalistic treatment adopted for the sides of this little amphitheatre across its back. Here something architectural was needed to carry on the scheme adopted in the centre, and, moreover, some dignified approach to the Mont Cavalier; so here we have a stately terraced stairway of marble rising to a broad balustraded upper terrace, from which we look over the whole lower garden, and again admire the vine-wreathed cliff, and see that its top (with which we are now on a level) is planted with forest-trees and laid out with winding walks.

So, too, is the whole steep, lofty side of the Mont Cavalier behind us. At the beginning of our century it was a burnt bare cone, its poor soil bearing only scattered tufts of grass and stunted shrubs. About 1820, thanks to the energy of the

*The historical facts in this sketch have been gathered from Monsieur L. Boucoiran's *Monographie de la Fontaine de Nîmes*, published in 1859. As the motto of his little book he quotes these lines from Ausonius:

Divona Celtarum lingua fons addite divis
Non Aponus potu, vitrea non luce Nemausus
Purior.

mayor whose name the hill now bears, it was planted to the top, chiefly with Aleppo Pines, which are mingled with Cypress and other trees, and near the paths a thick growth of shrubs. The walks are as thickly shaded as in a natural forest, and every now and then give us an enchanting glimpse of the lower gardens. About half way up they widen into a broad terrace-like path, running straight across the hill, and extending beyond the slope we have ascended, above a more precipitous slope, where a great retaining wall sustains it. Here one may pause to rest, to enjoy the beautiful prospect over the city.

Above this terrace the ascent is somewhat less steep and the paths straighter, and finally, when the relief has been well earned, we come out on a small, level, naked plateau, in the centre of which rises the famous Tour Magne.

This is a large and lofty ruined tower, evidently of Roman handiwork, which we can ascend for the sake of a magnificent panorama—Nîmes on one side, and a vast, green, broken, village-dotted plain elsewhere, encircled by distant hills, whose yellow bareness, contrasted with the green lowlands, gives us the full beauty of color that characterizes the *Midi* in midsummer. Surely nowhere else does so impressive a monument, looking on so magnificent a scene, give the finishing charm—literally the crowning charm—to gardens so lovely and so varied. Hardly in its perfect estate could the tower have been more impressive than now, an almost shapeless yet splendid giant, golden yellow and gray in color, and fringed all over with little flowering plants, among which here and there a young wild Fig-tree has taken vigorous root in some larger crevice. The hill-top around it is bare and encircled with a wall over which one gets views almost as fine as from the top of the tower itself.

Turning away at last, descending the forest-clad slopes in the brilliant sunset light and coming to terrace after terrace, we pause again on the lowest to note once more the effect of Maréchal's Rococo garden. We may abuse the Louis Quinze period as we will from the point of view of that "high art" which means serious intellectual work with brush and chisel. But it was a truly artistic period none the less—with clear ideals of its own and great skill in expressing them; a period which created works of genuine and individual beauty, though this beauty meant grace and charm rather than nobility and power. Above all, it was a period of decorative art, and nowhere did it find a better field than in gardening. The sins of those who made this garden and "improved" the Roman baths were great, according to the conscience of our archæological times. But they produced a wonderful new work of art, while, had we such relics of antiquity to deal with, we should only produce an out-door museum of relics.

A point to be noted, as in contrast to our northern ideas of garden-making, is that all this beauty exists with scarcely any use of grass. There are no lawns save the one bit which runs beneath the perpendicular cliff. Even flowers, against which the climate does not protest as it does against grass, play no important rôle, except in the shape of flowering shrubs. But for the intrusive beds already referred to, there are flowers only in a few places between the avenues, where little rectangular beds lie, surrounded with Box edgings. Gravel, marble, shrubs and trees—these are the elements with which the designer has worked. Yet the trees are so many and so fine that, while they do not interfere with the effect of the architectural features, they cover most of the garden with a cool green roof, and its general aspect, even in midsummer, is deliciously umbrageous and refreshing. When the trees are bare in the short midwinter of this region, the wisdom of planting so many broad-leaved evergreen shrubs must be manifest. But summer is the time to see the south of France. Then, and then only, it is truly the *Midi*; truly the enchanting half-way station between the real north and the real tropical south, combining the beauties of both, and vexing us neither by the cold rains and dull skies of the one nor by the unbearable heat of the other.

The Alleghanies of Virginia in June.

MOUNTAIN LAKE, the new name of the pretty little sheet of water which for nearly a century has been known by the herdsmen as Salt or Salting Pond, from the fact that they used to collect there to count and salt their cattle, is situated at the foot of Bald Knob, in Giles County, at an altitude of about 4,000 feet. The lake, as well as 100,000 acres of mountain and valley land around it, belongs to a gentleman in Washington, who also owns the comfortable hotel at its head. It is a mile long, closely surrounded by an almost impenetrable thicket of *Rhododendron maximum* and *Kalmia latifolia*,

and overshadowed by a few tall old Hemlocks and by high rocky ridges, which are covered by a young growth of White Oak and Black Birch.

The *Rhododendron* and *Kalmia* make such a display as they only make in the southern Alleghanies, many of them approaching twenty feet in height. The *Kalmia* was in bud and just beginning to bloom when we reached Salt Pond Mountain on the 30th of May. Great beds of *Viola blanda*, *V. primulaefolia*, and *V. cucullata*, with its variety, grow down to the water's edge on the sloping meadow in front of the hotel. It is the home of Violets. Two yellow ones, *V. pubescens* and *V. hastata*, are in bloom in the woods near by; *V. rotundifolia* and *V. sagittata* are ripening their seeds on the shady hill-side, and *V. Canadensis* has followed us up the mountain, where, in a swamp by the road, it is nearly a foot tall, the flowers large and showy, all the pretty white petals showing a delicate lilac beneath. *V. pedata* grows along the path to Bald Knob, and up there, on the exposed south side of the ridge among stunted patches of *Kalmia* and *Vaccinium*, is the prettiest of all, the light blue and velvety purple *V. pedata*, var. *bicolor*, as large and much more showy than the typical plant growing near it.

Bald Knob is about 4,500 feet in altitude, the highest of the Alleghanies of Virginia, it is claimed, and from the summit five states are said to be in sight. The view is very beautiful. The great ranges of mountains, stretching north into West Virginia and south into North Carolina, are all densely wooded as well as most of the valleys, though there are many small, poorly tilled farms scattered among the mountains. Bald Knob is at the end of a long rocky ridge, and is one vast flower-garden. The old gray rocks are covered with *Saxifraga leucanthemifolia* in full bloom, and deep down in a cool crevice the tiny *Asplenium montanum* has found a firm foothold in every crevice. *Heuchera villosa* is there also, and side by side grow *Ilex monticola* and *Ribes rotundifolia*. Further down on the slope another Gooseberry, *Ribes Cynosbati*, is ripening its curious prickly fruit.

On the ridge opposite, just above the lake, the flame-colored *Azalea* (*Rhododendron calendulaceum*) flaunts its gorgeous flowers. They are of every shade, from light lemon-yellow to the most brilliant fire-red, and make a great contrast to the pretty, delicate rose-pink flowers of *Rhododendron nudiflorum* which grows amongst it. Both *Azaleas* and the Mountain Laurel are abundant through the woods. The true Lily-of-the-Valley, *Convallaria majalis*, is everywhere under our feet; its white bells larger and most fragrant, its beautiful glossy leaves taller and wider than those of the cultivated plants at home. Its companion among the rocks is *Anemone trifolia*, a much larger and coarser plant than the delicate little Wind-flower (*A. Nemorosa*) that grows in low swampy ground near New York. Both *Clintonias* are here, *C. umbellata*, with its snowy umbels and broad shining leaves, and the less showy, but equally pretty, *C. borealis*, with its graceful clusters of light greenish bells, which later on will turn into conspicuous umbels of bright blue berries; and, abundant all through the woods, with their heads well up, in tall, stiff groups, are the curious fragrant flowers of the smaller yellow Lady's Slipper (*Cypripedium parviflorum*). The stemless Lady's Slipper (*C. acaule*) is as plentiful up on the mountain as it is in the sandy woods of Massachusetts and New Jersey. *Sedum ternatum* makes great mats on the rocks in the woods and is still in bloom, and near the top of the slope we come upon a great patch of the Painted Cup (*Castilleja coccinea*), its scarlet flowers making brilliant patches of color through the low growth of young Birches.

Trillium grandiflorum is the most common of the mountain flowers, and well deserves its specific name, though it varies so greatly in size and color that it seems hardly possible that the one name can fit all its forms. It is white, pink and a deep magenta, some of the great petals three inches long, others again not larger than those of the pretty, delicate little Painted Trillium (*T. erythrocarpum*) that grows with it. The Blazing Star (*Chamelirium luteum*) is very conspicuous, its tall, graceful white spikes often six inches long and three-quarters of an inch thick.

One of the most interesting among the flowering shrubs is *Crataegus coccinea*. We find two specimens near the road, one in full bloom, the other in fruit. The great bunches of large white flowers are a relief from the brilliant coloring all around us.

Above all this gay wild garden are some picturesque old White Oaks, their young pinkish leaf-buds and small gray leaves as beautiful as the flowers which run riot at their feet. The wind that sweeps unhindered over the ridge has twisted their branches into all sorts of fantastic shapes, and

the old lichen-covered trunks gleam white and silvery through the thickets of bright-colored Azaleas all around them.

In a little rill near the hotel, the tall, rather ungainly Lettuce Saxifrage (*Saxifraga erosa*) grows in the water, and in the adjoining marshy ground are the conspicuous triangular bright blue flowers of the common Spiderwort (*Tradescantia Virginica*). *Parnassia asarifolia* was found on old logs in the lake, but it was too early for the flowers, as well as for those of *Trautvetteria palmata*, which, in company with the green-flowered *Veratrum viride*, fills the deep bog along Little Stony Creek, the outlet of Mountain Lake, with a coarse, rank growth.

Magnolia acuminata is still in bloom on the borders of this swamp, and fills the air with the delicious fragrance of its large cup-shaped flowers, and all through the surrounding woods we found the curious *Conopholis Americana* in all stages of flower and fruit. The Striped Maple (*Acer Pennsylvanicum*) is dropping its small pretty racemes, and at its foot, growing all along the top of a decayed mossy log, are the dainty white flowers of *Tiarella cordifolia*.

These great logs, principally Hemlocks, overgrown with Moss and Fern, are the remains of what must have been a magnificent forest, for enough of them are still standing to bear witness to their former grandeur. In this jungle we find our third Trillium, the stiff, dark reddish *T. erectum*, and that curious vine, *Aristolochia Siphon*, which twines over rock and shrub, the queer, though hardly pretty, brown flowers really looking like so many little pipes among the large roundish leaves.

Both *Menziesia globularis* and *Vaccinium erythrocarpon* grow along the road over which we drive to the Cascade, five miles away, when we leave Mountain Lake on our way to the New River Valley. The falls are charming and the beauty of the ravine well repaid us for the rough climb we had to reach it.

There on the high cliffs we again found *Asplenium montanum*, but this time with feathery fronds three inches long, and we gathered *Cornus alternifolia* almost in the spray of the cascade. Two more members of the Birthwort family, *Asarum Canadense* and *A. Virginicum*, grew there in the deep Hemlock woods.

Gillenia trifoliata is another graceful white-flowered plant that has a place in the flora of Salt Pond Mountain, and such snowy clusters of the Deerberry's (*Vaccinium stamineum*) delicate little bells are surely rarely seen. In the woods near the foot of the mountain we found a small group of the pretty blue Scullicaps, *Scutellaria saxatilis*, *S. serrata* and *S. nervosa*, all growing not far from each other. Among the roadside trees *Tilia heterophylla* and *Magnolia acuminata* are prominent with many Oaks, and here and there are large clumps of the long, dark green leaved *Æsculus flava*, the latter with swarms of bees around its fragrant spikes of yellowish blossoms. Some of the larger trees are dying by inches in the fields, for the way of making clearings down there is essentially a lazy one. The underbrush is burnt or cut out, grain is sown, the trees are girdled and left to fall when and where they will. How any harvesting is done in such fields is a mystery to the uninitiated.

Our twelve-mile drive over an unspeakably rough road in wagons guiltless of springs came to an end at Eggleston's Springs, on the New River, where in a rather comfortless inn we spent the night.

New York.

Anna M. Vail.

New or Little Known Plants.

Schubertia grandiflora, Mart. and Zucc.

THIS species, which has recently been brought into notice in England, was first discovered by Martius some seventy years ago in the forests of eastern Brazil. A species much resembling this, but with rather smaller flowers (*S. graveolens*), has been occasionally cultivated for nearly fifty years, but has not received much attention. Like the very similar *Stephanotis floribunda*, it is a woody climber of the *Asclepias* family, with milky juice, and bearing umbels of large fleshy flowers in the axils. The leaves and branches are rather thickly covered with coarse brown hairs, and the bark upon the older stems becomes thick, white and corky. The flowers are pure white (becoming creamy) and extremely fragrant, and are very persistent, retaining their freshness for several days after being cut.

The plant is readily propagated either by seeds or cuttings, and is a rapid and vigorous grower, attaining a

length of twenty or thirty feet in the course of a year, and continuing in profuse bloom for several months. It bears a dry fruit of the size and shape of a small pear, covered with scattered fleshy spines, and containing numerous plumed seeds like those of the Milkweed. The leaves have a somewhat fetid odor, especially when bruised, which is the only thing that detracts from its value for floral purposes.

The genus *Schubertia* has been united by Bentham and Hooker with *Physianthus* under the older name of *Araujia*, but continental botanists still keep it distinct, perhaps more correctly. It is very closely allied to the "Condurango" which some years ago had an artificial reputation as a remedy for cancer.

The plant from which the figure here given was made was raised from seed planted in the spring of 1889 by Mr. John N. Gerard, of Elizabeth, New Jersey, and is now in possession of Mr. John Thorpe, of Pearl River, New York. The vine is now twenty-one feet long, trained horizontally, and covers a space three feet wide. It is flowering profusely both on leaders and laterals, the number of trusses being about 160, with from five to nine flowers in each cluster.

S. W.

New Orchids.

TRICHOPILIA PUNCTATA, Rolfe, is an elegant little species, allied to *T. laxa*, but the segments spotted with reddish purple, an unusual character in the genus. It was introduced from Costa Rica by Messrs. F. Sander & Co.—*Gardeners' Chronicle*, February 22d, p. 227.

CYPRIPEDIUM × CENONE, Rolfe, is a hybrid raised by Messrs. F. Sander & Co., from *C. Hookeræ* fertilized with the pollen of *C. superbiens*. The leaves are much like the former species, while the flowers have more of the character of the latter. The only plant saved is now in the collection of Mr. R. H. Measures, of Streatham.—*Gardeners' Chronicle*, March 1st, p. 260.

XYLOBIUM COLLEYI, Rolfe. This is the old *Maxillaria Colleyi*, Lindl., described in 1838, and which has long been lost to cultivation. A plant sent from the Trinidad Botanic Garden to Kew proved on flowering to be this species. Its native country still remains doubtful. It bears short racemes of reddish brown flowers, which smell like cucumbers, but are of little beauty.—*Gardeners' Chronicle*, March 8th, p. 288.

DENDROBIUM × ASPASIA, Veitch, is a beautiful hybrid raised by Mr. Seden for Messrs. James Veitch & Sons, from *D. aureum*, fertilized with the pollen of *D. Wardianum*. It was awarded a first-class certificate by the Royal Horticultural Society on March 11th. It is the plant described in the *Gardeners' Chronicle* for April 20th, 1889, p. 490, as *D. Wardiano-aureum*. The lip is very richly colored.—*Gardeners' Chronicle*, March 15th, p. 336.

CYPRIPEDIUM × NUMA, Veitch. A hybrid raised in Messrs. James Veitch & Sons' establishment from *C. Lawrenceanum*, fertilized with the pollen of *C. Stonei*. It has much of the general character of the pollen parent. It was awarded a first-class certificate by the Royal Horticultural Society on March 11th.—*Gardeners' Chronicle*, March 15th, p. 336; May 17th, p. 608.

CYPRIPEDIUM × OTHELLO, Veitch. A hybrid exhibited by Messrs. James Veitch & Sons at the meeting of the Royal Horticultural Society on March 11th. Its parents are *C. hirsutissimum* and *C. Boxallii*. Thus it must stand very near *C. × Godseffianum*, which has the same or the reversed parentage.—*Gardeners' Chronicle*, March 15th, p. 336.

ZYGOPETALUM (≠ BOLLEA) WHITEI, Rolfe, is a new species allied to *Z. hemixantha*, with cream-white flowers and a golden yellow disc. It is a native of New Granada, and was found growing with *Cattleya Mendeli*, by a collector of Mr. R. B. White, of Arddarrock. It is said to be a free grower, and the flowers are very pretty.—*Gardeners' Chronicle*, March 22d, p. 354.

ODONTOGLOSSUM WATTIANUM, Rolfe, is a very distinct form somewhat intermediate in character between *O. luteo-purpureum* and *O. Lindleyanum*, though whether it is a natural hybrid between them or a distinct species still remains doubtful. The flowers are yellow, blotched with maroon. It was introduced by Messrs. F. Sander & Co., of St. Albans.—*Gardeners' Chronicle*, March 22d, p. 354.

LÆLIA-CATTLEYA × HIPPOLYTA, Veitch, is a most beautiful hybrid raised from *Lælia cinnabarina*, fertilized with the pollen

Fig. 48.—*Schubertia grandiflora*.—See page 368.

of *Cattleya Mossiae*. The color of the flower is a beautiful Indian yellow, much like that of *Lælia + flammea*. It was awarded a first-class certificate by the Royal Horticultural Society on March 26th.—*Gardeners' Chronicle*, March 29th, p. 398, and April 5th, p. 431.

DENDROBIUM MIRBELIANUM, Gandich., is a very interesting species from New Guinea, which has been known to science for upward of sixty years, and has now been introduced to cultivation by *L'Horticulture Internationale*, of Brussels. It is a robust species with long, erect racemes of yellowish green

flowers, with a few purple-brown spots on the segments and lines on the lip.—*Lindenia*, vol. v., p. 49, t. 215.

MASDEVALLIA LOWII, Rolfe, is a pretty little species belonging to the Saccilabiate section, which was introduced from the Cauca, New Granada, by Messrs. Hugh Low & Co., of Clapton. It is readily distinguished from its allies by its shallow, maroon-purple lip, which is unusually fleshy and almost filled up with the keels so characteristic of this section of the genus. The sepals are also narrower than usual below, and gradually attenuated right to the apex.—*Gardeners' Chronicle*, April 5th, p. 416.

Kew.

R. A. Rolfe.

Plant Notes.

Hypericum Kalmianum and *Lobelia Kalmii*.

THIS is the season of *Hypericum Kalmianum*, whose yellow blossoms seem more than usually profuse the present year. Large patches of them may be seen covering the ground along the borders of the sloughs throughout the sand region at the head of Lake Michigan, for it is under such conditions that it flourishes here. The excellent figure and description of it in GARDEN AND FOREST for March 5th leads me to send some account of this plant and another one named after Peter Kalm, both of which are common near the shores of Lake Michigan in the sandy region just south and east of Chicago. One gets the impression from the habitats assigned in most of the hand-books of botany, that they are quite exclusively denizens of the rocks; but they flourish equally well in the damp silicious sands. The first named will also bear a considerable amount of dryness. It is not confined to the lake shore, though abundant in many places on the landward side of the ridge of sand usually fringing the shore, and against which the surf may beat when the waves run high. It sometimes spreads two or three miles away from the shore, growing along the borders of sloughs and sluggish streams. It may be found in company with our only shrubby *Potentilla*, *P. fruticosa*, though the latter can endure wetter conditions of soil, the lower part of the stems being under water sometimes, but not, apparently, as a permanent state. Such shrubs as *Pyrus arbutifolia*, *Cornus paniculata* and *C. sericea*, and the Willows *Salix lucida*, *S. glaucophylla* and *S. adenophylla*, often accompany it. The last is quite peculiar to the shore, seldom getting away from it, and is generally found higher up the slope of the sand ridge or on its top. I have found *Hypericum Kalmianum* in the same situations as *H. Canadense* and *H. gymnanthum*. Other plants growing along with it are *Linum Virginianum*, and *L. sulcatum*, *Castilleja coccinea*, *Tofieldia glutinosa*, the beautiful Gentian, *Sabbatia angularis*, and the two pretty Orchids, *Pogonia ophioglossoides* and *Colopogon*—each, of course, in its season. This partial list, which might be considerably extended, will serve to show that it is not very exclusive in its habits, for some of the plants mentioned are usually regarded as wet or damp-ground and some as dry-ground species. And it may also in a measure explain why this *Hypericum* is so easily cultivated, as well as the other species of the genus, since they readily adapt themselves to varying conditions. I should think, however, that a light soil kept reasonably moist would be nearest to their natural state. Some years ago I came across a patch of this plant in one part of the city that was at the time under improvement as a park. It had evidently been brought by accident among the roots of a White Pine which had been planted near by. The ground was sandy and quite dry, but the shrub was strong and doing well. I may add that *H. Kalmianum* is quite commonly distributed along the sandy shores of Lake Michigan, probably throughout its whole extent. The place where I have seen it farthest from the lake was on the rocks at the sandy Portage of the Menominee River, in the northern peninsula of Michigan. This is a little below Iron Mountain, or about fifty miles up the river from Green Bay, into which the Menominee flows.

The other plant named for Peter Kalm, *Lobelia Kalmii*, probably gathered by him at Niagara Falls, where it grows upon the rocks, as I have taken it from the Three Sisters Islands, is also common here. It is not confined to the "wet limestones," but does just as well in the damp sands, and sometimes assumes neighborly relations to *L. spicata*, abundant here in open sandy ground. A similar list of mingled plants might be made out for this, as in the case of *H. Kalmianum*, though I find it a little more confined to the wetter ground. In fact, an extended article could be prepared from material furnished by the mixed character of the flora of the upper lakes, especially that near the south end of Lake Michigan, interesting to the botanist, meteorologist, and doubtless profitable to the horticulturist, showing how plants in their

wild state readily adapt themselves to changed conditions, and I have often been surprised to find many strange neighbors among plants. In Michigan the habitats of plants differ widely from those set down in the books, especially when these wet, sandy grounds are drained as they come to be by the demand of the growing population of a large city. Having seen this go on for nearly a score of years, the opportunity has been very favorable to study this struggle for existence. While the original soil is left undisturbed by the plow or spade, the wet-ground and the dry-ground plants suit themselves to the altered surroundings, the latter coming in among the former, and as cosily occupying the same quarters as though they had never lived apart. Some are devoid of the requisite flexibility of constitution and yield to the inevitable, but many more soon come into permanent relations with a new environment.

Cultural Department.

Notes on Shrubs.

PROBABLY there is no species among the late flowering *Spiræas* in cultivation which would rank higher as showy ornamental shrubs than *Spiræa discolor* and its varieties. This species is a native of several of the states in the Rocky Mountain region, and it extends from southern California into British Columbia. Although long known it is seldom seen in gardens in this country; but, in the northern and New England states, this may be partly due to the fact that the plants generally do not withstand the severe winters without some artificial protection. *S. discolor*, var. *ariaefolia*, or, as it is more often called, *S. ariaefolia*, is very unequal in its behavior at the Arboretum. It has seldom flowered so well as it has this season, a circumstance partly due, no doubt, to the past mild winter, and to the stems having been bent over and carefully, though lightly, covered with soil.

The tallest stems have attained a height of eight or nine feet, and all have been well laden with numerous large, loose spreading panicles of creamy white or straw colored flowers. The panicles bear some resemblance to those of the common Siberian *S. sorbifolia* of our gardens, but they are not so large and have a more feathery and less stiff and formal appearance. Besides this, they differ in being produced on a number of lateral branches along the main stems, whereas the panicles on *S. sorbifolia* are erect, solitary and terminal.

The two species bear no resemblance to each other in habit or in general appearance, and if it was perfectly hardy *S. ariaefolia* would be considered the most valuable, both for its blossoms, and because it may be very easily kept as a neat, trim bush, and does not spread and encumber the ground by suckers.

Under cultivation at the Arboretum the panicles of flowers average about six inches in length by four inches across, but some are nine or ten inches long, with a diameter of from six to eight inches. The individual blossoms are small, about a fifth of an inch across, and they are light creamy white in color. The odor has been described as like that of Sweet Birch, yet to many people it is more strongly suggestive of honey. There is also a suggestion of the odor of Chestnut-blossoms, which lends a slightly disagreeable quality.

In its native habitat the shrub is said to grow from five to fifteen feet high. In well sheltered situations in southern New England it would probably rarely fail to blossom abundantly, and some hardier strains than that grown at the Arboretum may yet be procured. The flowers are of short duration, but, as all the panicles do not develop their blossoms simultaneously and some plants are a little later than others, a good show of bloom is kept up for three weeks after the opening of the earliest blossoms—about the 1st of July.

Spiræa Millefolium, which was figured on p. 509 of the second volume of GARDEN AND FOREST, blossoms at the same time as, or a little later than, the last species, and although more interesting in many ways it has little merit as a conspicuous or decorative shrub. The specimens in the Arboretum were produced from seed collected in Nevada and they have proved very hardy without any protection. They are, however, of straggling habit, though upright, and only three or four feet in height. The foliage is not sufficiently abundant to hide the naked lower portions of the branches and stems. The narrow, finely twice-pinnate leaves distinguish this species from all others of the genus. Another peculiarity of the leaves is that a very well developed tuft of them remains on the tip of each branch throughout the winter, and these leaves continue their growth with the new shoots in the spring.

The panicles of flowers are not produced in much profusion. They are from two or three to four or five inches long, and are borne on the extremities of a few of the strongest shoots. The petals are of a rather pale white color and the expanded flowers are nearly half an inch across. But as not one-half of the blossoms in a panicle are open at any one time they are not so showy as they otherwise might be. The fragrance of the flowers reminds one of the odor of the common Yarrow, though the latter is much less powerful, while that of the leaves and whole plant has been likened to creosote and also suggests burning sealing-wax.

This species and *S. discolor* have so many characters peculiar to themselves that some systematists place them in separate genera as being quite distinct from the true *Spiræas*.

In *Spiræa Douglasii*, another species from the western part

well known Japanese *Spiræa callosa* and many of its forms come under this class, but they are valuable because they keep up a succession of blossoms for several weeks.

Arnold Arboretum.

J. G. F.

Notes on American Plants.

WE have in New England three native Sundews (*Drosera*) which flower about this season. They are all small species, generally classed among the carnivorous plants, and this curious characteristic is one of their chief points of interest. Yet the largest of these, the Thread-leaved Sundew (*Drosera filiformis*), has numerous handsome rose-purple flowers half an inch wide in a one-sided spike. It is seldom more than a foot high. The very long, thread-like leaves are covered with their

Roman Baths, Gardens of the Fountain, Nîmes.—See page 366.

of the continent, we have a plant which nearly corresponds to our Hardhack or Steeple-bush (*S. tomentosa*). Except for the slightly larger size of the panicles of its flowers, which may also sometimes be a little deeper in color, *S. Douglasii* possesses few qualities to make it of any more ornamental value. The plant is of larger, coarser growth, and the leaves are also larger but not so neat and attractive as those of the common Hardhack, which also bears neater, much more pointed and more symmetrical panicles of flowers.

The variety of *S. Douglasii* known in nurseries as *S. Nobleana* chiefly differs from the typical species in having the flowers arranged in panicles which are broad and spreading instead of narrow and pyramidal. The very short duration of the flowers and the fact that those on the upper portion of the panicles usually become an ugly brown sooner than the lower or outer blossoms is a serious drawback to the beauty of these and some other deep pink or rosy purple flowered species. The

glandular bristles, and the sticky gluten which exudes from them catches many an unfortunate insect that comes within reach of it. In fact, the leaves are often almost hidden by its little victims. This species has been found near the coast at Plymouth, Massachusetts, and thence southward to New Jersey and Florida.

Our most common species, the Round-leaved Sundew (*D. rotundifolia*), is a more delicate little plant, with round leaves on spreading petioles which lie quite near the ground. The flower-stem is seldom more than eight inches high, bearing several small white flowers. It is very common in peat-bogs and wet sandy places throughout New England.

The Long-leaved Sundew, formerly called *D. longifolia*, but now known to botanists as *D. intermedia*, var. *Americana*, is not so common, but grows in bogs, in wetter places, and might almost be called an aquatic. In its general appearance it much resembles the preceding, and it has similar white

flowers. All of these Sundews are easy to grow, but the first, when brought from as far south as Florida or Georgia, might not endure our cold winters without protection. They thrive well in a wet sandy soil with the Venus' Fly-trap and such *Sarcenias* as are found in sandy bogs.

The common Floating Heart (*Limnanthemum lacunosum*) is a valuable little aquatic, and is especially adapted for small aquaria. Its round, heart-shaped leaves, usually a little more than an inch long at this season, are of a reddish purple shade and variegated with a greenish centre. The several small white flowers are a third or half an inch wide on thread-like petioles, which come from about an inch below the leaf. They succeed each other in long succession, and, like the leaves, float on the surface of the water. It is a native of shallow ponds from Canada to Florida.

The value of our native white Water Lilies for cool waters cannot be too highly estimated. The sweet-scented one, *Nymphaea odorata*, is already too generally known to need any mention. Its variety, Minor, with smaller leaves and flowers, is also a desirable plant, and may be grown with it in similar situations. The largest of our Water Lilies, *N. tuberosa*, is not so generally known. It is a larger and stronger plant, and when given an equal chance bears larger and handsomer flowers—nearly a third larger than *N. odorata*. The leaf is also a third larger, not rarely fifteen inches wide. The flower, though not so strongly scented as the other, has a delicate and delicious odor peculiar to itself, and it remains open later in the day after those of *N. odorata* have closed. Both sides of the leaves of *N. tuberosa* are green, while in all the plants of *N. odorata* I have seen the under side of its leaves were of a reddish purple color. The pinkish color of the sepals, so common in *N. odorata*, is said to be always lacking in *N. tuberosa*, and the small tubers, which are so numerous in *N. tuberosa*, attached to the main root-stalk, are lacking in the other.

There are other handsome species native to North America, such as the *N. flava* of the southern states, with yellow flowers, the beautiful blue flowered *N. elegans* from southern Texas and Mexico, and the *N. ampla* and *N. gracilis*, but none of these thrive in our cool, clear waters of New England. Even in the hottest summer weather, such as the present season affords, they only manage to exist, sending up a few weak leaves with no promise of flowers.

One of the most attractive little plants of the Heath family, and which is now in flower, is the Spotted Wintergreen (*Chimaphylla maculata*). The plant is seldom over six or seven inches high, and bears four or five nodding, white, deliciously fragrant flowers, three-fourths of an inch wide. The ovate-lanceolate leaves are dark green, variegated with a lighter centre along the middle the whole length of the leaf. It is a difficult species to transplant, and the only way is to take up large sods and set in a fine shaded soil.

The White Fringed Orchis (*Habenaria blephariglottis*) is just beginning to bloom. It is one of the rarest and most desirable species we have. It grows in bogs and on borders of ponds, usually only a foot high, with oblong-lanceolate leaves, and at the summit a short, round spike of pure white flowers. It is a good plant for artificial bogs, and blooms a little before *Habenaria psycodes*, when flowers are few.

Aletris farinosa (Star Grass) has its leaves in a cluster close to the ground, from among which comes a long, slender, naked scape, two or three feet high, bearing a wand-like raceme of pretty white flowers. The spike or raceme is about three-fourths of an inch in diameter and five to eight inches long. It is useful for cutting. The plant is not rare, and may be easily grown in the sun or shade in a sandy soil.

Silene stellata, Starry Campion, sometimes called Colic Root, is an attractive plant when in bloom. Its numerous flowers are three-fourths of an inch across and pure white. The petals are cut into a fringe, which adds to its beauty. The stems are two or three feet high and rather weak at time of flowering, for the stalks with flowers are usually bent down. The taper pointed, narrowly ovate leaves are in whorls of four at considerable distances apart along the stem. It is a native of wooded banks from Rhode Island to Wisconsin and southward. Although it grows in shade or partly shaded situations it seems to thrive equally well in the sun.

The Bristly Sarsaparilla or Wild Elder (*Aralia hispida*) is not a showy plant. The stems, which are a foot or two high, are bristly, with a moderate amount of foliage, and terminate in a head bearing several hemispherical umbels of greenish white flowers. Its best season is when in fruit and it bears an abundance of dark berries much resembling those of the common Elder. It grows in rocky places, also on dry sandy soil, and does fairly well in either sun or shade.

Southwick, Mass.

F. H. Horsford.

Cinerarias.

CINERARIAS are among the most useful and showy plants for the embellishment of the conservatory and greenhouse during the winter and spring months. They are easily managed, too, but are seen much more rarely than they deserve, and still more rarely grown up to the recognized standard of a florist's flower. One great drawback to the successful cultivation of Cinerarias in the United States is that growers follow the cultural notes given in European periodicals and catalogues. Rules which ensure success in England would bring disaster if strictly adhered to in this country, and yet these plants can be grown successfully by every one who can command an ordinary garden frame and a greenhouse from which frosts and excessive damp can be excluded.

Cinerarias are classed as greenhouse perennials, and many varieties are grown as such in Europe and propagated by offshoots after flowering; but the difficulty here is that the plants cannot survive our summer sun and heat. This fact must also be borne in mind by those who treat them as annuals. Plants from seed sown in May and June lack the vigor of later sown seedlings, and this is a vital point in cultivation. Seed of an extra good strain should be obtained from a reliable source, and two sowings made; the first from the middle to the latter end of July, with another about three weeks later. The seed should be sown in pans or shallow boxes upon light sandy soil, moist, but not wet, and they should be covered lightly with finely sifted soil. A cold-frame, pitched north, with sashes shaded and a bed of coal ashes two or three inches thick, makes a good place for seed-pans, as well as for the seedlings in all stages of growth, if no other suitable structure can be commanded. The seed-pans should be covered with glass or paper to prevent evaporation during the day, but the glass must be taken off for some time daily, as the close atmosphere will help the development of bench-fungus, which will destroy the seedlings before they can be safely handled. I prefer to cover the pans during the day and leave them uncovered at night. In watering seed-pans a fine rose watering-pot or a rubber sprinkler should be used. When the seedlings are large enough to handle, prick them off into shallow boxes and return them to the frame, where they should be constantly, but discreetly, ventilated. Newly pricked off or potted plants must be kept somewhat close for two or three days after shifting or the plants may flag, a result to be avoided always; and yet the night air is beneficial. Keep a sharp look out for slugs and snails, as the tender seedling is a tempting morsel, and if one slug can reach a plant at this stage it is gone. Young toads also like to bury themselves in the cool sandy seed-boxes, not to the benefit of the plants.

As soon as the plants are large enough, and before they get crowded in the boxes, pot them off singly into three-inch or three-and-a-half-inch pots, using well decayed sod and rotted cow-manure or manure from a spent hot-bed. The soil should be rubbed through a sieve of half-inch mesh with sharp sand, broken charcoal or coal ashes to keep it porous. The pots must be clean and well crocked for drainage. Care must be taken in handling the young plants from the seed-pans that a leaf is not broken or the tender roots bruised by pressing the soil too firmly into the pots. The plants may be lifted with a stout label with as much soil as will adhere to the roots, and should not be planted too deeply or they may rot off. As soon as the plants have partly filled the pots with roots they should be shifted into five-inch and six-inch pots. In the latter size they may be left to bloom, but those in the smaller pots will need another shift. Use the same soil as at first potting; give a light sprinkle of bone-meal and place the pots once more in the cold-frame, giving attention to shading, watering and ventilation.

As the plants advance in growth those in five-inch pots may be shifted into pots two or three sizes larger, using the same compost as before; those in six-inch pots should receive weak liquid manure once a week, and the application should be increased in strength and frequency as the plants require watering, until every second watering is with liquid manure. Give each plant abundant room for developing its foliage, and use every possible means to keep the foliage clean, healthy and vigorous. During hot and dry weather a light sprinkling overhead will greatly assist them. As autumn approaches every precaution must be taken against frost, but the plants should not be hurried into the greenhouse, for mild weather is often experienced after a light frost or two.

The Cineraria dislikes sun heat and fire heat and extremes of temperature, and when it is necessary to bring the plants into the greenhouse place them in the cool house, giving air on all favorable occasions, but guarding against cutting draughts of cold air, a glaring sun and a dry atmosphere. A

mean temperature of forty-five degrees should be maintained, and, if kept cool, Cinerarias are seldom troubled with insects. In heated structures they soon become infested with green fly. A mild fumigation with Tobacco-stems should be given weekly as a preventive, for if green fly is not kept off the plants the flowers will not be worth seeing. The plants should be kept growing steadily and rapidly from the seed until they flower. This is essential, and therefore they should be kept clean and healthy, and should never be allowed to become dry, starved or pot-bound.

Staten Island.

The Vegetable Garden.

EACH year's experience with the little Bush Lima Bean sent out last year by Peter Henderson & Co. confirms my first impression of its great value; and I had an opportunity to observe it before its dissemination. This Bush Lima is a variety of the Small Lima Bean, and it originated in Campbell County, Virginia. Its small size was a disappointment to many who bought it for the first time, but its earliness, remarkable productiveness and good quality will atone for this. It is a well known fact in the south that the old large Lima is very unproductive anywhere south of the Potomac, and the small Lima, known south as the "Butter Bean," has always been a favorite sort here. The Small Bush Lima ought to be a favorite in the north, on account of its earliness, which prolongs the season for this delicious vegetable. Here in Raleigh we can have the Bush Lima in abundance by the middle of June, nearly a month earlier than the large pole Lima is ready, and the same difference will probably hold good at the north. This season a pint of these beans planted in my garden has given an abundant daily supply to a family of twelve persons since the middle of June, and as I write (July 19th) there is no let up in the blooming and pod-making. I believe now, though disposed to doubt it at first, that a larger yield per acre can be had from the bush than from the pole bean of the same species. This will be accurately tested at the Experiment Station here next year.

Flat Strap Leaf Turnips for family use should not be sown too early. These Turnips, when in perfection, which is only in autumn, are the sweetest and best for table use. They should, however, be grown almost as rapidly as radishes to be good. If sown too early in highly enriched soil they grow large and pithy and are not so sweet. The middle of August at the north is early enough, and a month or more later in this latitude is better. The seed should not be sown broadcast. We usually open furrows with a plow, when they are grown on a large scale, about two and a half feet apart. In these furrows a heavy dressing of superphosphate is sown and a light furrow turned from each side over the first one, forming a sharp ridge. A roller is then run over the ridges lengthwise, flattening them nearly to the soil level. The seeds are then sown with a drill on the flattened ridges, and over the fertilizer.

The black flea beetle (*Haltica*) attacks them as soon as they germinate, but a dusting of air-slaked lime will usually expel them. If the lime alone is not sufficient, use a very small portion of Paris green, say one-half of one per cent. of the whole.

The Chinese Rose Colored Winter Radish can also be sown in the same way and at about the same time, or, better, a little later. In this latitude these are best when sown the last of September, and a second sowing can be made later still if the first ones promise to be too large. We leave them to stand where they grow for winter use protected only by the Chickweed, which here mats over every fertile spot in winter. Even in the north I think they might be left where they grow and covered with a heavy coat of straw or forest-leaves. They keep well in moist sand in a cool cellar.

The earthing-up of Celery should not be begun too early, except of a little for fall use. Celery earthed and blanched in hot weather is not usually a good article. Whenever the winters are not too cold the bed system practiced around Baltimore is best. These beds are six feet wide by any length, and the plants are set in rows across the bed a foot apart and six inches in the rows. The whole bed is earthed up en masse and finally covered with forest-leaves, and the plants are allowed to stand where they grow. Celery grown in these beds has a crispness which is not found in Celery that is lifted for storing in winter. Even at the north Celery could be kept if a rough board roof were thrown over the banked base and then covered with straw to exclude the frost.

The dwarf Celeries are best at the north, but south of the Potomac the half dwarf and the old large sorts are the best. In this latitude our chief difficulty is to get it to stop growing. Last winter being unusually mild, our Celery nearly all ran up to bloom and seed in midwinter.

The practice of growing a late fall crop of Irish Potatoes, I believe, is destined to extend not only in the south, but a good deal further north than the experiment has hitherto been made. Years ago, even in the south, a late crop of Irish Potatoes was a very uncertain matter. But we have learned how to grow them here with certainty, and by the use of southern prepared seed Potatoes the planting could be extended with profit northward. The best practice here is to take Potatoes of the early crop and spread them out in a light shed until well greened by the light. These are then bedded on a piece of mellow ground in beds of any convenient width about the middle of July, the Potatoes being laid just so as not to touch each other. The bed is then covered with two or three inches of soil, and left until planting time, which is here from the middle to the last of August. By this time all the immature potatoes will have rotted or dried up, and the good ones will be well sprouted. These are then planted in shallow furrows, without cutting, and covered with not more than two inches of soil above the potato. The earth is packed to them with a roller, and in the after culture more soil is drawn to them. Growers in the latitude of Philadelphia, by taking these southern grown potatoes and planting in the middle of July, could, I feel sure, raise a fine crop. They should plant the seed potatoes much more thickly, to allow for the rotting, which we do in the beds. The chief point to observe is to cover these late planted potatoes very lightly. Deep planting at this season will always give a bad stand. Southern potatoes, well greened, could be shipped at low rates, since the cuttings of the early crop are the ones generally used.

Agricultural Experiment Station, Raleigh, N. C.

W. F. Massey.

The Dewberry.

IN the issue of GARDEN AND FOREST for July 9th Mr. Jack writes: "In a wild state the fruit (of the Dewberry) is very variable in size and flavor, but by selection and under cultivation it is possible to produce berries which, for size and flavor, cannot be distinguished from some of the best blackberries."

One would infer from this paragraph that the dewberry at its best is equal in point of size and quality to the best blackberries, a statement which does scant justice to the delicious, melting juiciness of the dewberry. To my own taste this fruit is surpassed in quality by the strawberry alone.

Except in form and color the dewberry differs nearly as much from the blackberry as from the raspberry. Its time of maturity is between the two, being at its best just as the raspberries are failing and before the blackberry-season has really commenced.

The Dewberry does not succeed well in all localities. In my first trials, which were with Bartell's and the Mammoth varieties at Geneva, New York, the plants were quite unproductive, and the fruits filled out very poorly. In the summer of 1889, however, I saw a plantation of Bartell's Dewberry on the farm of Hon. H. C. Adams, of Madison, Wisconsin, that convinced me in a moment that there is a future for this fruit. The vines were well loaded with the beautiful, glossy berries, many of which were nearly or quite two inches in length, and by the side of them the finest blackberries appeared commonplace indeed. And they were superior in taste as well as in appearance. Mr. Adams told me that he had no difficulty in securing several cents more per quart for them than for blackberries.

There is certainly a promising field for work in the improvement of the Dewberry. Seedlings of it may be grown with the greatest ease, and require but a short time to come into bearing. The difficulties of cultivating this fruit are little greater than in the case of the Strawberry. The fact that the stems are trailing is an advantage in cold climates, as they are the more easily protected in winter and are more likely to be sheltered by snow. One grower mentioned the fact that the vines of the Dewberry form a natural hiding-place for serpents, and in localities where these abound he has found difficulty in inducing timid pickers to gather the crop.

University of Wisconsin, Madison.

E. S. Goff.

Erpetion reniforme.—This pretty little Australian Violet will not prove hardy in the colder states, but any one who has the protection of a greenhouse to give it in winter will be delighted with the abundance of modest little blue and white flowers all through spring and summer. Our plants were raised from seed sown in October last, and kept in the greenhouse all winter, where they commenced to flower in April. The plants form numerous creeping stems, from which come a dense mass of small green leaves, and flowers on stems about two inches high. These latter resemble other Violets, except

that the inner half of each division of the flower is blue and the other half white, giving them a distinct beauty of their own. *Erypetion reniforme* is the name usually given the plant in seed lists, though there are several synonyms, the most common of which is *Viola hederacea*. This plant would be desirable for carpeting the flower border in summer, but owing to its delicate habit it should not be set among coarse-growing plants or in dry places, and for growing in pans it cannot be over-praised.

Californian Lilies.—So far as I have tried these lovely Lilies, in all sorts of soil, in sun and shade, in open ground and in frame, *L. Washingtonianum*, *L. Humboldtii*, *L. Columbianum*, *L. rubescens*, *L. parvum* and *L. maritimum* have all been most unsatisfactory garden plants. There must be some conditions necessary to their successful culture that are yet insufficiently known, and I am tempted to ask if any readers of GARDEN AND FOREST have been able to succeed with these beautiful western Lilies for any length of time. *L. pardalinum*, when not affected with disease, grows here in Massachusetts often five feet high, with a beautiful display of its spotted flowers. That this Lily should do so well, and the other kinds so indifferently, requires a little explanation from those who are familiar with the plants and their natural surroundings.

South Lancaster, Mass.

E. O. Orpet.

Nymphæa rosacea is another of Monsieur Marliac's introductions well worth growing. It is apparently a variety of *N. odorata*, which it resembles in habit and foliage. The flowers are a light, clear rose or pink, in form and size like the type. Compared with *N. odorata rosea* (the Cape Cod Lily) the color is much more delicate and less decided. *N. rosacea* will prove a charming addition to any collection.

Nymphæa pygmæa alba (*tetragona*), the smallest of the Water Lilies, is a native of western China and Siberia. Owing to its diminutive size it may be grown in very limited space, the leaves being only three to four inches in diameter. The flowers are plentiful, white, about two inches in diameter, and of rather thin texture. Grown with other Nymphæas, in shallow water, they add variety, and their appearance is all the more dainty among the more robust growers.

G.

The Forest. The Sihlwald.—I.

IT was my good fortune recently to pass a month in the Sihlwald, as that portion of the forest-property of the City of Zurich is called, which stretches for some five miles along the narrow valley of the Sihl. It is not often that a forest is so favorably situated both geographically, and as to the conditions which determine the value and fertility of timber-lands; and while there are many peculiarities in its management which mark it as distinct from the great body of European forests, it exhibits so full a knowledge of forestry applied to such excellent conditions and so admirable an adaptation of means to ends, that if it fails of being typical of that which is, it may assuredly challenge attention as the illustration of that which ought to be. Further, since during the last fiscal year it yielded to the city a net revenue of more than eight dollars per acre, a short account of it may serve to emphasize the fact, so often lost sight of, that the protection of forests is not an end, but a means, and that the whole question of forestry has a very definite and important financial bearing. It has, therefore, seemed that a few words upon the Sihlwald might not be without interest to the readers of GARDEN AND FOREST, and I purpose, after describing it briefly in the present paper, and sketching the management of the forest in a second, to touch upon it in a final one as a piece of municipal property.

Situated about two miles inland from the western shore of the Lake of Zurich, and within an hour's drive from the city, the Sihlwald lies along, and for some distance fills, the valley of the Sihl. The stream from which the forest takes its name was once a dangerous torrent, but in the progress of the work on the more rapid water-courses, which has already cost the Federal Government eight million dollars and the canton of Zurich rather more than eight dollars per head of its inhabitants, it has been "corrected" into harmlessness. Walled in along a large proportion of its course, and with its drainage area protected by forests and the heavy turf of the Swiss pastures, it has abandoned its aggressive character to become the centre of the industry and prosperity of the valley which it waters. The soil of the valley has for its geological base a marly sandstone, overlaid, on the broad plateaus which break the moderate slope of the left bank, by a sandy clay of glacial origin, deep, rich, and with great capacity for holding water.

The opposite slope, much steeper, and, in consequence of its south-western aspect, more directly exposed to the action of the sun, is drier and less fertile. But since the whole valley of the Sihl, or at least that part of it which here concerns us, lying as it does between altitudes of 1,624 and 2,986 feet, enjoys an annual rainfall of fifty inches, it would be a mistake to speak of the right bank as dry and infertile, except in comparison with its richer neighbor. Both slopes are intersected by numerous small ravines, from which no fewer than forty rivulets find their way to the Sihl. But with the climate of northern Europe indicated by a mean temperature of forty-eight degrees Fahrenheit, and with the conditions of soil and moisture which have been mentioned, the exceptional productiveness of the Sihlwald would still remain partly unexplained, were it not possible to add that the land which it covers has been uninterruptedly under forest for something over a thousand years. That precious condition of the surface which the French and Germans unite in describing as "forest-soil," so slow in forming and so quick to disappear wherever the full sunlight is allowed to reach the ground, has here been produced in perfection by centuries of forest-growth. It is perhaps to this factor, next to the abundance of humidity, that the high annual yield of wood in the Sihlwald is due.

The growth which covers the soil thus fortunately suited to its needs is a mixed high or seedling forest, in which the deciduous trees largely predominate. Under the law of the rotation of forest-crops, not so well known as that which determines an analogous success in agriculture because it acts over vastly longer periods, the character of the mixture has undergone a gradual change, until, in the course of two centuries and a half, the percentage of coniferous trees has declined from sixty-one to fourteen, and the deciduous forest has taken their place. The composition of this last on a typical area of the Sihlwald may be taken to include eighty Beeches, ten Ashes, nine Maples and one Elm in every hundred trees. No exact data are available for the sixteen conifers which should theoretically find their place among these hundred broad-leaved trees, and it can only be said that they would stand thus: Spruce, Silver Fir, Scotch Pine and Larch, in the order of numerical importance. But it is to be remarked that the distribution of the different species is very far from being as regular as this statement would imply. While the mixture is in general rather one of individuals than of groups, still the various trees form each a larger proportion of the forest in those localities which best meet their requirements. Thus conifers replace the deciduous forest upon the dry slopes and sunny exposures of the right bank of the Sihl, and even considerable bodies of pure Spruce are to be met with. Nor does the Sihlwald, in spite of its large annual yield, convey the impression of a dense forest. The trees, cut soon after the period of maximum mean annual growth, commonly exceed a hundred feet in height at the time of felling, but so slender are they that it is rare to find a specimen of a greater diameter than two feet at twice that distance from the ground. The leaf-canopy, lifted on the straight, clean boles far above the beautifully kept paths, which it has been the policy of the Forstmeister to maintain, has none of the gloomy effect which a lower cover frequently produces; and the absence of underbrush and fallen branches gives a feeling of space and cultivation which is pleasant in the extreme.

Scattered along between this forest and the Sihl, are the houses of Forstmaster (Forstmeister) Meister and his assistants. Here, too, are placed the saw-mill, handle factory and injection plant, whose presence as integral parts of the equipment of the forest, chiefly distinguishes the management of the Sihlwald from that of other similarly situated European woodlands.

Nancy, France.

Gifford Pinchot.

Correspondence.

Experiments in Producing Rain.

To the Editor of GARDEN AND FOREST:

Sir.—"In certain villages in the Indian Central Provinces, besides the village blacksmith, the village accountant, the village watchman and the like, there is an official termed the Gapogari, whose duty it is to make rain. So long as the seasons are good and the rain comes in due time his office is, no doubt, a pleasant and lucrative one. It is not laborious, and it is obviously the interest of all to keep him in good humor. But if, as sometimes happens, the hot dry weather of April and May is prolonged through June and July, and week after week the farmer sees his young sprouting crops withering beneath the pitiless hot winds, public feeling is wont to be roused against the peccant rain-maker, and he is led forth and

periodically beaten until he mends his ways and brings down the much-needed showers."

This quotation from Blanford, the meteorologist, is used by a correspondent of the *Evening Post* to introduce the statement that the official position of Gapogari is to be established in this country. At least this may be inferred from an amendment by the Senate made in the appropriations for the Department of Agriculture.

Whether the methods of imposing the fine for non-performance are to be the same as in India I cannot surmise, but for the sake of the unfortunate official who is charged with the production of rainfall let us hope they are not. This much difference, at least, appears to be made, that the methods of producing rainfall are to be found by experiment, and not to be left to be a secret of the unreliable Gapogari.

There is in the appropriations for the Forestry Division a provision calling "for experiments in the production of rainfall," for which the vast sum of \$2,000 is set aside. One is inclined to think, at the first look, that this was inserted by some one desirous of breaking up the modest beginning of Government forestry interests by demanding proof positive and on the spot that forest and rain-fall have a relation to each other, but inquiry develops the fact that this is a bona fide proposition, and the experiments are expected to be made. Forestry has really nothing to do with it, for it is dynamite, guns, electricity or what not, that is to serve in the solving of the problem.

Senator Farwell, of Chicago, is referred to as the originator of this remarkable proposition, and he may have a special interest in the experiment. He is one of a syndicate who built the Texas state capitol, one of the finest and most substantial architectural works in this country. In payment, the state ceded to the syndicate 3,000,000 acres of land in the so-called Pan Handle, a region which for a large part is devoid of living water (except where the Canadian River traverses it), and which suffers also from deficient rainfall. Rain would make it bloom, for it is very fertile soil. Hence a Gapogari might prove a desirable officer in the Pan Handle.

If Mr. Fernow, the Chief of the Forestry Division, whose unfortunate task it will be to explode the clouds (or is he to furnish clouds, too, for \$2,000?) will be the most famous man of this century, if he succeeds in filling the position satisfactorily, and will not need to drudge at making forestry acceptable to the nation.

When asked about the matter he did not express himself very hopeful of success, and while admitting that the subject was not altogether devoid of legitimate inquiry, he did not think that our knowledge of physical forces and meteorological phenomena was as yet equal to the task, and he felt an unwillingness to try experiments without having investigated the basis for them. He said that the idea of producing rainfall artificially had been ventilated for a long time, and the hopeful expectation of solving the problem had been encouraged by the observation that cannonades on battle-fields or at celebrations (fireworks on a large scale), prairie fires or other extensive conflagrations were apt to produce precipitation for reasons well understood. But the application of this experience for practical purposes seemed questionable, especially in such parts of the country where there is no moisture to precipitate. An honest effort, however, will be made to arrive at least at a possible basis for such experiments, and to spend the money which, it was evident, the Chief of the Forestry Division would have preferred to use on the legitimate field of his division.

Washington, D. C.

M. C.

The Crandall Currant.

To the Editor of GARDEN AND FOREST:

Sir.—A late number of GARDEN AND FOREST contained some notice of this Currant in connection with the remarks upon new fruits by Mr. H. E. Van Deman, Pomologist of the United States Department of Agriculture. At the meeting of the nurserymen in New York in June, Mr. Van Deman spoke favorably of the Crandall as a new variety of Black Currant, of large size, with less of the strong odor peculiar to its class, and consequently better flavored. The most important fact, however, was brought out by Professor L. H. Bailey, of Ithaca, New York, which was that there was no one distinct variety that could properly be named Crandall, as the plants sent him were evidently a lot of mixed seedlings diverse in character, some bearing large and others quite small berries. It was stated that Mr. Crandall had grown a quantity of seedlings from the Missouri Currant, and that parties had obtained and propagated from a lot of these mixed seedlings plants to which they gave the name "Crandall," instead of selecting, as they should

have done, a single plant, and propagating stock from it for a new and fixed variety.

The Crandall, as described and illustrated by those offering it for sale, has very large berries, and is represented as remarkably productive. Its peculiarities seem to be small and scanty foliage, with many small clusters, with three to five or six berries to the stem. Samples sent me, for testing, from the introducer, indicated that Professor Bailey was probably correct as to their mixed character, as their average was scarcely up to that of the Black Naples. There were a few quite large berries, many medium, and more very small. Raw or uncooked they had no attraction for me, and when stewed with fine sugar none of my family cared to eat them. Their introducer claims that they are excellent made into pies; but I should not place them high in the scale for any purpose, as compared with raspberries, blackberries, or even with other currants. It is but fair, however, to say that I am not very partial to Black Currants; and unless the character of the Crandall can be improved and fixed, by growing it from a single selected specimen plant, I certainly should not regard it as worthy of introduction. In its present condition I think Mr. Van Deman was inclined to commend it above its merits.

Delaware, Ohio.

George W. Campbell.

The Utah Black Currant.

To the Editor of GARDEN AND FOREST:

Sir.—You inquire (page 352) whether this is still under cultivation? You will find it in every edition of our catalogue for the past twenty or twenty-five years, and we suppose plants must be growing all over the Union. It is now over its fruiting season; but I enclose a branch from a yellow fruiting plant. The berries are nearly double the size of the ordinary Missouri Currant; but the most careful examination fails to find any specific difference between it and the eastern form of *R. aureum*. Our stock originally came from Mr. Siler, then of Saint George's, southern Utah.

When in Salt Lake City in 1873 our party was received very generously by the Mormon people, and one of them, Mr. Jennings, gave us the freedom of his beautiful garden. The Black Currants were then growing in great quantity, and they were nearly as large as we grow Houghton Seedling Gooseberries here. The flavor was delicious, and I think most of our party gathered them by the handful, and enjoyed them hugely. But I have never found them so piquantly toothsome here, nor are the fruits so large and tempting. They seem to require the dry soil and arid climate of the central regions of our country.

I have seen notices of this Crandall Currant for a year or more past; and desiring to try everything, sought last spring to buy a few hundred somewhere. But after reading the statement that it was a variety of the Missouri, and suspecting its identity with our own Utah Black and Utah Yellow, we felt very thankful that we had failed to spend our money.

If careful comparison shows the form more lately introduced to be identical with the Utah Black it would be advisable to drop the name of "Crandall."

Germantown, Pa.

Thomas Meehan.

Recent Publications.

Annals of Horticulture in North America, for the year 1889. By L. H. Bailey. New York: Rural Publishing Company. 12mo; pp. 249.

This is the first volume of a proposed series of year-books, which are intended to make a current record of horticultural progress. The first half of the book treats of such general subjects as the yields of various crops for the year with their prices, the newer fruits which are adapted to special localities, recent tendencies in ornamental gardening, the diseases of plants, insects injurious to plants, horticultural work in the Department of Agriculture and in the Experiment Stations, with notes on the transactions of the more important horticultural associations in the country. Many of the articles in this part of the book have been prepared by specialists and some of them have been taken from the leading horticultural journals of the world.

The last half of the book is devoted to special annals, the most important of which will be considered the list of plants introduced in 1889, a catalogue of kitchen garden vegetables which were offered for sale in North America in 1889, and the plant portraits which have appeared during the same year. It will hardly be questioned that a carefully prepared year-book of this sort will have great value for reference and it will become of greater value as the years pass on. This particular

volume, as Professor Bailey explains, has been somewhat hastily prepared and naturally he has not had the co-operation of the horticulturists of the country to such an extent as he should be able to count upon hereafter when the enterprise has become an established success. One is hardly disposed, therefore, to search for any shortcomings in the book, but rather to welcome it as the beginning of a series which will prove of substantial value to American horticulture. We are glad to note the promise that the scope of the succeeding volumes will be broader so as to include more of European horticulture.

Perhaps the chapters of most value are those which deal directly with plants of the year. The list of kitchen garden vegetables seems very complete and it will furnish invaluable material for studying plants in the future. It ought also to serve a good purpose in preventing the duplication of names. In looking over the catalogue of plant portraits for 1889 we observe that some half dozen of the portraits which have appeared in this journal during the year have been omitted. Some of these are important, as, for example, the portraits of *Croton Alabamensis*, *Philadelphus Lemoinei* and *Yucca elata*. We observe also that none of the illustrations in the *American Agriculturist* have received any credit; but no doubt such errors will be less frequent in the succeeding numbers.

Notes.

Eighty million feet of timber were contained this year in the annual "drive" of logs sent down the Connecticut River, most of it being consigned to Holyoke, Massachusetts.

A large part of the cranberry picking on Cape Cod is now done by Portuguese, both men and women being employed. There are now more than a thousand of these immigrants in Provincetown, forming about one-fourth of its population.

Hollyhocks, single and double, formed the chief feature of the Massachusetts Horticultural Society's show in Boston on July 19th. Mr. Joseph S. Fay, of Wood's Holl, sent the largest contribution, while those of Mr. C. F. Curtis, of Jamaica Plain, Messrs. Edwin Sheppard & Son, of Lowell, and Dr. C. G. Weld, of Brookline, were also remarked.

The Japanese Box Elder (*Negundo cissifolium*), which has been flowering and fruiting in this country for several years, seems to be a most desirable tree for the borders of a small lawn. It is a round-headed tree, with clean, thick foliage, and it is strikingly beautiful in midsummer on account of the delicate color of its young shoots, which continue to grow after most other trees have finished their growth for the year.

One objection to *Nymphaea tuberosa*, of which Mr. Horsford speaks in another column, is that by the production of tubers it multiplies so rapidly that it will soon fill a large pond, and may crowd out plants of less aggressive vitality. Mr. Gerard finds that *N. Marliacea* is also prolific of tubers, so that it will soon be within reach of every one, and it, too, may prove a dangerous competitor in the struggle with other aquatics.

In his article on Botticelli, published in the *Century Magazine* for August, Mr. W. J. Stillman says with reference to the artist's picture of "Spring," where the foreground turf is thickly dotted with the common flowers of Tuscan meadows: "The non-occurrence of the Anemone, now one of the most splendid attractions of the flora of Tuscany, in this collection of flowers, which is painted with almost scientific exactitude, is considered as a proof of the late arrival of that flower from the East, and that it did not exist there in the time when this picture was painted. It is certain that if it had been known in the fields of Florence its conspicuousness of form and color would have made it impossible to leave it out of this gorgeous *hortus siccus*."

The house once occupied by Governor Endicott, which was recently torn down in Salem, Massachusetts, was one of the oldest in the commonwealth. It is said to have been first framed in England, then brought across the ocean and set up in Gloucester. In 1628 it was purchased by Endicott and taken apart, removed to Salem and rebuilt on what is now the corner of Washington and Church Streets. After the Governor's death in 1665 it was still for some time occupied by his family, and for a while the sessions of the General Court were held within it. Afterward it was moved a short distance away, and went through many vicissitudes, its last service having been as a storage-house. Its timbers were found to be of English Oak of great size and still in apparently perfect condition.

Bulletin No. 10 of the Minnesota Experiment Station speaks as follows with regard to the bagging of Grapes: "The varieties treated were Delaware, Early Victor and Brighton. The fruit was bagged with paper bags when about the size of small peas. At the harvest, the bagged grapes were better in every case than those not bagged, but the most marked difference was with the Brighton, the bunches of which were clean, perfectly colored, and the sweetest grape I have ever eaten. Those exposed were not so good in any way, being very dusty and uneven in ripening. In our previous trials with Concord and Worden and some other varieties, the result has been uniformly in favor of the use of bags as a covering." The cost of bagging was estimated as varying from a quarter of a cent to one cent a pound.

In answer to a question, Mr. F. W. Burbidge writes in *The Garden*: "The first *Cattleya* ever introduced into Britain was *C. labiata*, found by Mr. William Swainson in the Organ Mountains, Brazil, and brought to England in 1818. On this plant Lindley founded his genus *Cattleya* in honor of the late Mr. W. Cattley, of Barnet, one of the first amateurs in England to form a collection of Orchids. Mr. Cattley died in 1832 and his plants went to the collection of Mr. Knight (now Veitch's) at Chelsea. If this true old *C. labiata* exists wild now in Brazil, its locality is unknown, and it has not been imported for forty years or more. Sander has had men hunting for it for years, but it is now believed to be extinct. In cultivation it is rare and valuable, and is known as the old autumn-blooming *C. labiata* or *C. labiata vera*. Botanically, however, all the *Cattleyas* are now considered as geographical forms or varieties of the old *C. labiata*. It has a robust constitution, as is proved by its having lived on so long in our collections, since the last importation came nearly half a century ago."

In an article recently published in *Nature* it was stated that "as far as known at present the Roses of western Asia have no Sanscrit name and were not known in ancient India. Yet *Rosa Damascena* is grown on a large scale for the manufacture of Rose-water and essence of Roses throughout northern India as far as Ghazipur, in twenty-five degrees north latitude. It is not impossible that the western Roses were introduced into India by the Mohammedans. As there is no Sanscrit word, so is there no original term for the Rose in Hindoo. In most Indian languages the cultivated Rose is called *gūl*, which is the Persian name. It is called *gūlāb*, which really means Rose-water, unless, indeed, as sometimes stated by Munshis in India, *āb* in this case is a suffix with no separate meaning. In addition to their local names, some of the wild Roses of Himalayas are often called *gūlāb*, *bān gūlāb* (the Rose of the Forest or Wild Rose). These facts seem to us of interest, as illustrating that wide-spread influence of the Persians which has been dwelt upon in the articles on the History of the Art of Gardening which have recently been published in GARDEN AND FOREST.

The New York *Sun* recently contained a long description of the Vanderbilt estate near Asheville, North Carolina. Not only the magnitude of the enterprise but the intelligence with which it has been undertaken puts it at the head of all contemporary enterprises of the kind in this country. Five thousand acres with a frontage of four miles on the French Broad River were purchased by Mr. George Vanderbilt in a region famed for beautiful scenery and a delightful climate. Messrs. F. L. Olmsted & Co. were employed to aid in choosing and preparing a site for the house, instead of being called in—as is so often the case with landscape-gardeners—after the architect had done his work. The house, which Mr. R. M. Hunt will build, is to be of Indiana limestone, and, with its connected offices, nearly 500 feet in length. It has been designed in an Italian Renaissance style, and one façade will be supported by a retaining-wall rising thirty feet from the face of a hill-side, commanding a superb distant mountain view. Clay is abundant in the vicinity, and a brick-making plant has been set up, as two or three million bricks will be needed for the house and its dependencies, in addition to tiles for the underdraining of the land. Other materials will be brought to the spot by a branch railroad two and a half miles long, constructed for the purpose, from the nearest station. The intervale lands on the river are to be farmed, while of the hill lands fully four thousand acres are to be improved as a forest under the advice of the landscape architects. It bids fair to become, in a few years, one of the most interesting places in America for the lover of rural life on a lordly scale to visit, and one which will represent not merely a large outlay of money, but the intelligent co-operation of great wealth with the best science and the highest art that the time affords.

National Parks.

LAST week we spoke of the necessity of some immediate action to save a remarkable grove of Giant Sequoias in Tulare County, California, and since the paper was published we have received a petition addressed to Secretary Noble, in which the facts we published are set forth with the prayer that the land may be withheld from entry until Congress has an opportunity to act upon the matter. The petitioners desire that Congress shall set apart this particular group of Big Trees, which are scattered over some four or five square miles, together with certain other outlying groups, as a "national park," to be devoted to public use forever. There is little doubt that the sentiment of the country would favor such a consummation. The Mariposa Grove, it is true, has been reserved, but this is comparatively small and isolated. The other forests of these Big Trees are disappearing with frightful rapidity. The Fresno trees are already condemned, and the mills are running now which will soon convert them into lumber. It is lumber, too, which the speculators want who have recently obtained possession of much of the Sequoia lands in Tulare County, and, of course, these trees must go. It is to be remembered, too, as John Muir points out in the current number of the *Century*, that more trees are wasted in these mill operations than those which are actually made use of, because, after the manageable trees have been cut and blasted and sawed, fire is let loose among the refuse to clear the ground, so that the trees which were too large to be converted into profitable lumber are destroyed as well as the saplings and seedlings. As we have often said before, the vast herds of sheep in these mountain pastures create a desolation even greater than that caused by the axe, and here, too, the fires which are kindled to improve the pastures sweep through the forests from end to end, and these groves of mammoth trees will soon be nothing but a memory unless some legal protection is thrown about them. It must be admitted that our experience with so-called "national parks" hitherto has not been encouraging. One has only to read the defense of the management of the Yosemite Park by the Governor of California to be convinced that its scenery has been mutilated and defaced almost beyond the power of restoration.

But if any additional evidence was necessary the illustrations of Mr. Muir's article above referred to will furnish it. Here we see soft expanses of meadow turned into plow-land and the stumps still standing and still sound of some 2,000 thrifty young trees which have been cut away for some unknown purpose. Besides this total destruction of the trees we see beautiful groups of young conifers disfigured into the likeness of German toy-trees by having all their lower branches ruthlessly lopped away. There are rising murmurs of complaint to the same effect regarding the Yellowstone Park, and even the Niagara Reservation, which is in the heart of a civilized country and embraces so small a space that it can all be easily and constantly inspected, is only kept from being hopelessly vulgarized by constant watchfulness on the part of the people.

It is perhaps a misfortune that all lands set apart for public use should be designated by the name of "park," a word which suggests to most people some attempt at gardening or decoration. This proposed reservation will be primarily a forest and it should be so designated. Certainly it should not be called by a name which has come to be adopted as a common title for fair grounds, race tracks, play grounds, city squares, groups of adjacent private residences, and many other things equally incongruous. It is plain that any attempt to dress out a Sequoia forest with ornamental planting or floral finery would be ridiculous. What is needed in such a place is the preservation forever of the essential natural features of the scenery. The motto of the association whose work brought about the law for the Niagara Reservation was "To preserve the Scenery of Niagara." This, in a broad sense, should be the aim in administering the Yosemite, the Yellowstone, and the Tulare Forest. No other justification for taking possession of these places in the name of the people is needed than an honest effort to preserve, as we have inherited them, these treasures of beauty and sublimity, of majesty and mystery, of grandeur and of grace, and to transmit them unimpaired to our posterity.

But while everything like artificial embellishment should be avoided in the preparation and management of these representative pieces of scenery, there is an opposite danger to be shunned. It is too often assumed that because a place is to be treated naturally, it can therefore be successfully administered by men who have no special aptitude or training for such work. It is admitted that study should be given to a work of landscape art in which artificial arrangement and construction prevail, but it is taken for granted, on the other hand, where a simple and natural treatment is desired, that no thought or study is demanded. Therefore it happens that Governors and others who have the appointing of executive officers for the administration of Reservations like the Yosemite feel that they do their whole duty if they only select men of energy and honesty and business ability. But the fact is that the problem of preserving as nearly as possible the original and natural expression of a given piece of scenery is quite as difficult a one as the creation of a landscape picture out of the raw material. It is a general truth that, in every work which makes appeal to the æsthetic sense, simplicity of conception and of treatment is an essential condition of the highest success and is the crowning proof of genius. And in this special case it is plain that only an artist of the first rank is able to decide what are the essential and enduring features in a given passage of scenery and what are merely temporary and adventitious. It will not be enough to let the trees alone in the Tulare Forest. It must be adapted to human convenience. Roads must be prepared and other arrangements made so that it can be seen, and seen by great numbers of visitors at all seasons, and to the best advantage always. And these arrangements must be made not for to-day, but for all time, and during this time the forest will be constantly changing. Trees will grow and trees will die, and it will require the exercise of the keenest foresight to make a preparation which will best meet these

ever shifting conditions so that the forest will be preserved and maintained, and at the same time prepared for use without showing the touch of man. Work must be done, but it must be work which conserves without blemishing, and work which will make all these forest-treasures available without defacing one of them. Such a task requires as much ability as the highest creative or constructive work of the landscape-gardener. No one is equal to it who does not possess the faculty of the true artist and who has not learned to have a reverence as well as a love for Nature.

Botany at the University of Montpellier.

THE readers of GARDEN AND FOREST have already read accounts of the celebration in May of the six hundredth anniversary of the foundation of the University of Montpellier. To botanists this celebration had a special significance, for, since the foundation of the Botanic Garden by Henry IV. in 1593, and the installation of Richer de Belleval as Professor of Botany, the picturesque university town has been the home of a large number of illustrious botanists. In 1889 there was established at the university an *Institut de Botanique*, and, in a very interesting pamphlet, Professor Charles Flahault gives an account of the buildings erected and of the courses of instruction, together with short biographical notices of the prominent persons who have either occupied the chair of botany or pursued their botanical studies at Montpellier. The list is long and includes an astonishing number of illustrious botanists. Amongst them are the names of Rondelet, Clusius, Lobelius, Bauhin, Magnol, Tournefort, A. de Jussieu, Draparnaud, A. P. DeCandolle, Delile, Duval, Bentham, Moquin-Tandon, Charles Martins and others well known in the history of botany. Besides those mentioned are other names known rather in the literary than the scientific world. Rabelais, the pupil and friend of Rondelet, who introduced his master under the name of Rondibilis in "Pantagruel," we are told was not a very zealous pupil, and Rousseau we are informed was more occupied with his health than his studies while at Montpellier in 1737.

The Institut occupies three principal buildings in the Botanic Garden: the Pavillon Richer de Belleval, including the rooms devoted to instruction; the Pavillon Magnol to research in anatomy and physiology; and the Pavillon de Candolle containing the herbarium, library and the office of the Director of the garden. The equipment for general instruction is liberal, but we notice with special pleasure the ample provision made for research and the facilities offered to those who wish to consult the very valuable collections belonging to the University. One room in the Pavillon Magnol is reserved for visiting botanists who wish to pursue botanical investigation. It is to be hoped that the day is not far distant when, in America, it will be generally recognized that the botanical resources of our universities should be so administered that those who wish to pursue research will find abundant opportunity and encouragement. The plan adopted at Montpellier deserves careful study and should commend itself to all American universities as a model to be followed by them as far as their means permit.

Much of the wastefulness in the methods of cutting timber now in use in this country is a matter of habit, a survival from the times when the chief need was to destroy timber as fast as possible in order to clear the ground for cultivation. It is easier to go on in the same way than to change, and much timber is now wasted that would yield a profit to the owner if it were rightly handled. Many lumbermen recognize the need of change in the direction of greater care in cutting and in the handling of timber lands, but they leave the work of beginning the use of new methods to those who are to come after them. It is often asserted that regard for their own interests will lead lumbermen and owners of timber lands to guard against waste whenever such care becomes necessary. But it is

necessary now. It would be good economy, would be profitable in all cases in which reasonable care is lacking. The fact is, as all competent observers of human action are aware, that men in general are very far from being controlled by an intelligent regard for their own interests. Enlightened self-interest is an entirely adequate principle for the guidance of human conduct, but to bring men to accept it, and to act upon it, has always been a matter of great difficulty. It requires much discussion, reiterated precept, and often the sharp lessons of painful experience, to persuade men to do what is most profitable to themselves, to adopt such courses of action as will yield them the greatest benefits.

The need for improvement does not usually become plain to everybody at the same time. It is more apt to be perceived by a few at first, and earnest and long-continued effort on their part is often required to awaken others to a sense of its importance or necessity. Not only are men long indifferent to what they afterward recognize as necessary and fortunate for themselves, but they strenuously resist the effort to bring about changes from which they are to receive the principal advantages. This experience is always being repeated. It is a constant feature of human life and action. It is all exemplified in the matter of methods of forest-management in this country. Greater care in avoiding and preventing waste would be profitable now. The time has already come to practice it. Lumbermen can make more money by it this year and the next than they do by the methods now too commonly used. Such reasonable care would increase the value of their timberlands so that they would sell for more or be more valuable property as an inheritance for their children. No matter how abundant our timber supply may be, or how long it is likely to last, it would be wise and profitable to avoid wasteful methods of cutting timber and of handling timberlands. It is only sensible and practical economy to employ all available means and conditions to increase the productiveness of wooded lands, and to make the local timber supply everywhere last as long as possible.

Native Shrubs of California.—IV.

Lavatera assurgentiflora, Kellogg (Proc. Calif. Acad., i, 14). The number of things I shall have to say about this *Lavatera* will be out of proportion to its merits as an ornamental shrub; for these are not great. A stout and heavy-looking bush or small tree, with a not unsightly, angular, Maple-like foliage, and a profusion of rich red flowers hung on long and slender stalklets from the axils of the leaves, it is sufficiently showy to have been cultivated everywhere throughout the maritime parts of California, apparently from the early days of the Spanish settlements.

Unquestionably indigenous to Californian territory, it is never seen growing wild except around old dwellings or near gardens; and, since along with the Acacias, Eucalyptus and other Australian trees and shrubs, it comes into flower soon after the winter solstice, a stranger would take it for an exotic from the southern hemisphere. Such was the impression it gave me when I first saw it, blooming beautifully in midwinter, many years ago. It is one of a considerable number of trees and shrubs which are found wild nowhere else, in the world except upon two or three rocky islets which, although politically a part of California, are barely visible above the horizon as one looks out to the seaward, on a clear day, from Santa Barbara or San Pedro.

When Dr. Kellogg named and published the species as new to science, he put upon record a tradition that the seeds of it had been brought in the first place from the island of Anacapa. It does not appear that any botanist or amateur had authenticated this supposed habitat; nor has such authentication ever yet been made. On the contrary, several intelligent men who, although not botanists, know the *Lavatera* very well, and who have been on Anacapa repeatedly, declare that it does not grow there. I nevertheless suspect that if ever a zealous and careful botanist shall visit Anacapa he may find it lurking among the half-cavernous niches of the basaltic columns not far above the water's edge. It should be sought in some such place, and not on the dry and exposed summit or sides of the island, where other shrubs grow,

The exact type common in cultivation all up and down western California has, within a few years, been found on one or two maritime rocks smaller than Anacapa and lying near the large island of Santa Catalina. But the principal native locality for the species is the island of San Miguel, the northernmost member of the Santa Barbara group, and an island two or three miles in extent. But the shrub of San Miguel differs in several ways, and quite notably, from that which is in cultivation, and which came from the more southerly station. It is of more robust and compact growth, making a shapely and handsome small tree; its leaves are much larger, its flowers of a deeper red, and the stellate pubescence, prevalent in the malvaceous family, is far more abundant.

On my return from San Miguel Island in 1886, I felt some suspicions that the *Lavatera* might be proven indigenous to the peninsula of San Francisco. Although 300 miles of sea intervene, the soil and climate of the two localities are much alike. I had seen it flourishing in abundance at the Cliff House in wild looking places among the bluffs overhanging the sea, and also, as I thought, in places among the sand hills rather remote from where it was likely to have been planted. I had also been informed by older members of the California Academy that it had been still more common years ago than now at various places back of San Francisco, where there were no settlements. But having revisited and carefully inspected every locality there, I became convinced that it is not indigenous on any part of the peninsula of San Francisco. The largest trees, and those appearing as if they might be twenty years old or more, are either under cultivation and where they were planted by the hand of man, or else in the vicinity of old dwellings. It is very commonly planted in rows along the western and northern sides of market-gardens, where it speedily grows into an effective hedge, which, while not dense enough to be impervious to animals, serves a useful purpose in breaking the force of the cold sea winds which prevail from those points of the compass during the summer.

The leaves and twigs, abounding in mucilage, are a nutritious and wholesome food for sheep and cattle, which are very fond of them. On San Miguel the only trees surviving in 1886 were certain large-sized ones, which bore their branches above the reach of any ruminant. The smaller ones were dead or moribund through having been too closely browsed by the sheep.

The individual flower of this species is really very beautiful; and it is only because the branches are a little coarse and unwieldy, and the foliage apt to conceal the richest profusion of the flowers, that the shrub as a whole is not highly attractive. The petals, an inch long or more, arranged as in the Hollyhock or Mallow, are of a peculiar deep pink color, veined with almost a carmine. On first unfolding they spread apart only so far as to form a bell-shaped corolla, afterward becoming abruptly deflexed from a little above the base, so that the body of the corolla is inside out; and since the flowers are pendulous, each on a long, slender stalklet, this inversion of the corolla gives the fullest exposure of the stamens and pistils to the favoring agency of the winds. The seeds, which are under all circumstances matured in abundance, germinate freely where they fall; and so the species spreads wherever planted, if not too far from the sea. In the interior of the state I have never seen it.

Although none of the other three North American species of this genus are properly Californian, inasmuch as they inhabit each an island of its own off the coast of the Mexican territory of Lower California, still they must be mentioned in connection with *L. assurgentiflora*, and I name first of the three *L. venosa*, confined to the little island of San Benito, the position of which is about 500 miles south of the islets occupied by the best known species. And while an intermediate islet has yielded a third, and a very different species, the two which belong to those widely separated extremes of our *Lavatera* archipelago, although so distinct that no botanist having seen them both will be likely to think of them as very closely related, they are far more like each other than either one is like either of the two whose geographical range is intermediate. This is another strange fact to be noted in connection with this capricious sorosis of sea-rock shrubs.

L. venosa has about the same foliage as that of *L. assurgentiflora*, though of a deeper green, with even less pubescence. Its flowers are also hung each upon a long and slender peduncle, but they are rather more than twice as large, commonly measuring three inches from tip to tip of the widely spreading petals. The color of the petals is mainly white below the middle, of a rich violet above, about five heavy veins of the violet streaking the otherwise white portion of the organ down to its base. The leaves being rather smaller than

those of *L. assurgentiflora*, and the flowers twice as large, it is far more showy; and the individual flowers are greatly admired by the few who have seen them. Two years ago some small seedlings were brought to me from San Benito by a friendly naval officer whom I had asked to do me the favor, and the one surviving individual of the lot, now blooming luxuriantly at Berkeley, is doubtless the only one alive upon this or any other continent. Its mode of growth is altogether peculiar. There is always an erect main stem, from which the branches take a descending instead of an ascending or even horizontal direction, so that the trunk is ultimately concealed by the leafy and flowery branches whose tips reach the ground and then turn up or spread or straggle about. My bush having been continuously in flower since the beginning of February, promises now a crop of seeds. It seemed to endure the slight frosts of our "Bay region" about as well as does its familiar ally, whose native station is far more northerly than its own.

L. insularis, of the Coronado Island, seven miles off the coast of northern Lower California, and *L. occidentalis*, of Guadalupe Island, are more robust shrubs than either of the aforementioned, and their stout branches, short and firmly ascending, combine to form a low, umbrella-like head; their large greenish and violet-streaked corollas are strictly bell-shaped, inserted on short peduncles, and are mostly concealed by the foliage. The essential distinction between these two, as species, lies in the foliage, and is one which an amateur might overlook, although the eye of a practical botanist would quickly both catch the marked difference and recognize its specific importance. In *L. insularis* the five or seven lobes of the leaf radiate all around the end of the leaf-stalk, giving quite a star-shaped outline to the whole. In *L. occidentalis* the lobes all incline forward in such wise that the leaf is rendered digitate or hand-shaped. These two species, each restricted to its own island, and the two islands more than 200 miles apart, form a group by themselves, both having gray-green foliage, short-stalked violet and green flowers, with corollas broad and open even to the base, but not recurved or reflexed; both also have that compact habit which, making display of the handsome pointed foliage, compensates for the concealment of the flowers.

It is a curious fact that, while *L. venosa*, the home of which is nearest the tropic, endures well the winter of the latitude of San Francisco, *L. insularis*, whose locality is only thirty miles below San Diego, is more tender. Of two specimens of the latter which I brought to flowering here from seeds gathered while on Coronado in 1885, one was killed by frost two years ago, and the other succumbed a year later.

But the main charm of these shrubs is that which they possess in the eye of the student of plant geography. The genus *Lavatera* belongs to the Mediterranean region of the Old World, where there are perhaps twenty species. There is one in Australia. On the continent of America not one occurs. On a few Pacific coast islands and islets lying at distances of from seven to twenty-five miles from the mainland, we have three, with a fourth on another which lies at a greater distance.

That all these species, even when transferred to the latitude of San Francisco, begin their new growth and exhibit their flower buds about Christmas, comes of the fact that the climate they are all used to is in effect a tropical one. On their respective insular shores they all grow at a little distance from the water line, where the temperature is as mild and equable as possible and where there is never the slightest frost; and there is no island on all the coast whose vegetation does not seem to be about three weeks earlier than that on the adjacent mainland.

The three southerly species here spoken of, as yet almost unknown except to two or three Californian botanists, will be slow in getting into cultivation. The open air climate of San Francisco, even, is rather too severe for them; but on account of their great botanical interest as well as for their singular beauty they are sure to receive further attention.

Foreign Correspondence.

London Letter.

LILiums were the principal feature at the last meeting of the Royal Horticultural Society. Mr. H. J. Elwes delivered an address of exceptional interest, both botanically and horticulturally. As monographer of the genus, and as a cultivator of the plants for many years, Mr. Elwes has special claims to be heard on the subject of their botanical differences and their requirements under cultivation. Whilst few will be found to decry Liliums as ornamental plants, there are

many who find their cultivation difficult. A large proportion of the species are unsatisfactory as a rule, the few cases of their good behavior in the garden being quite exceptional. It may be said with regard to not a few of the species, that we are as yet ignorant of the conditions essential to their permanent welfare in the garden. This is proved in many ways. For instance, we find those who are lucky enough to succeed with the majority of *Liliums*, declaring that certain given soils and conditions are bound to prove suitable for those plants which others fail to grow. But when these named soils and conditions are carefully provided, even then it often happens that success does not result. Many good gardeners fail with such species as *L. auratum*, *L. Brownii* (*Japonicum*), and even *L. speciosum*. At Kew, where many rare species are a success, *L. candidum*, the glory of thousands of cottagers' gardens in England, is a failure; *L. longiflorum*, too, is far from satisfactory in the open air. On the other hand, *L. auratum* is a giant both in stems and flowers, giving no trouble whatever. Such rare and usually "miffy" species as *L. tenuifolium*, *L. Parryi*, *L. Krameri* and *L. Leichtlini* are equally satisfactory. The commoner species are abundantly represented, and, as a rule, thrive most satisfactorily. This success has not been attained at once, but only after repeated experiments in different parts of the garden and in different soils. The best results are the outcome of planting the bulbs amongst the loose-growing shrubs in deep beds of good soil. Fungoid diseases have given some trouble lately, and it has been suggested that leaf-soil is often the cause. One great bulb-grower in England has convinced himself that leaf-mould, as prepared and used in England, is the curse of the bulb-garden, and has given up its use entirely.

Mr. Elwes, in his monograph published in 1880, recognized fifty-two species of *Lilium*, almost every one of which has been in cultivation at one time or another. In his address last week he dwelt specially upon the fact that notwithstanding their long cultivation in gardens, and their readiness to produce seeds, yet the number of hybrid *Liliums* raised is very small. Many have tried to procure hybrids, and some have publicly declared their success, but the only well marked hybrids hitherto raised are *L. Parkmanni*, the result of crossing *L. auratum* and *L. speciosum*, and which was obtained in Massachusetts some twenty years ago. A second hybrid is the offspring of *L. Dalmaticum* and *L. Hansonii*, raised here by Mr. Powell. To these must now be added one called Francis Fell, and exhibited last week by Mr. Ware, of Tottenham. It is the result of crossing *L. Parryi* with *L. pardalinum*. Unless for the purpose of giving vigor and a stronger constitution to some of the weaker kinds, there does not appear much need for hybrid *Liliums*, the genus presenting an exceptionally wide range of variation in size, form and coloration of flower as well as in habit and season of flowering.

Collections of the flowers of *Liliums* were exhibited by some of the most noted growers. In addition to the new hybrid already mentioned, Mr. Ware sent flowers of *L. Bolanderi*, a new kind allied to *L. maritimum*, with glaucous leaves in whorls, and small flowers, the segments narrow, reflexed and colored purplish crimson, with blotches of a darker shade. It is a distinct and pretty little plant.

Zinziber D'Arceyi was exhibited as a new plant from the South Sea Islands by the Messrs. Veitch. It has leaves variegated with white and creamy yellow, and promises to be a useful little foliage plant for the stove.

Masdevallia Schraderiana is an attractive little species with fleshy erect leaves and an erect flower-scape. The flowers are an inch across, with three long tails; the upper portion of the segments is purplish in color, the lower part white, edged with purple, the tails being dull yellow. Baron Schröder obtained a first-class certificate for it.

Cypripedium Youngianum is the produce of *C. superbien*s and *C. Ræbeleni* and is a superior hybrid. Its petals are five inches long and narrow, white with greenish lines and thickly spotted with purple-crimson, the margins fringed; the sepals are of the same color, but flushed with crimson instead of being spotted; the lip is hairy and colored pale brown. It was exhibited by Messrs. F. Sander & Co., and was deservedly awarded a certificate.

Zygopetalum crinito-maxillare is a remarkable hybrid, its parentage denoted by the specific name, and possessed of characters which combine those of its parents. The flowers are about the same size as those of *T. maxillare*, the sepals and petals deep green spotted with brown, the lip deep violet-blue. It was sent from the gardens of Lord Rothschild and obtained a certificate.

Aërides J'Ansoni is the name given by Mr. Rolfe to a plant

lately introduced from Burmah and flowered by Messrs. Hugh Low & Co., of Clapton. It belongs to the group represented by *A. odoratum*, and is in fact merely a variety of that species, viewed in a broad sense. For garden purposes it is, however, sufficiently distinct to merit a name. Mr. Rolfe thinks it may be a natural hybrid between *A. odoratum* and *A. expansum*. It is looser in habit and narrower in leaf than an ordinary *A. odoratum*. The flower segments are tipped and spotted with bright rosy purple, and the spreading lateral lobes of the lip are transversely barred with the same color. The plant flowers freely in a small state and the flowers are decidedly pretty in form and color.

NEW LATE-FLOWERING HARDY AZALEAS.—Mr. A. Waterer, of the Knap Hill Nurseries, has succeeded in raising a new race of hardy Azaleas, which promises to be particularly valuable on account of the lateness of its flowering season. In England the flowers of hardy Azaleas generally are over early in June, the latest to flower being *A. occidentalis*, which is sometimes gay with bloom well on into July. By using this as a breeder and crossing it with some of the larger flowered, brighter colored kinds, Mr. Waterer has obtained a number of very handsome seedlings which bloom in July. I have lately mentioned the glorious effect produced in a few gardens here by the flowers of the hardy Azaleas in June. Mr. Waterer has given these plants an additional value by raising a number of late-flowering varieties which will continue the flowering season some weeks beyond the time the older kinds have hitherto lasted.

London.

W. Watson.

New or Little Known Plants.

Clematis Fremontii.

THIS handsome herbaceous *Clematis* is the western representative of the rare *Clematis ochroleuca* of the eastern states. It has simple or occasionally branching, pubescent stems a foot or a foot and a half high, with large, crowded, leathery leaves, which are sessile, broadly ovate, entire or few toothed, sparingly villous on the lower surface, with very conspicuously reticulated veinlets. The flower is terminal and nodding, with thick purple, narrowly lanceolate sepals an inch long, with tomentose margins and recurved tips. The pedicel becomes erect in fruit which is composed of silky akenes with short tails naked above and silky at the base. The fruit is handsome, although less showy than that of its eastern congener.

*Clematis Fremontii** was discovered by Frémont on his second expedition, his specimens having, however, no note of locality. The plant was not seen again until 1874, when it was re-discovered by Dr. Louis Watson, near the town of Ellis, in western Kansas. It is now known to grow from Missouri and Kansas to the mountains of Colorado. *Clematis Fremontii* is very hardy; it is easily raised from seed and may be increased by division. It thrives in ordinary garden soil and flowers during the first days of June.

Our illustration is made from a plant grown in the Arnold Arboretum, where it was sent several years ago from Colorado by Mr. T. S. Brandegee.

New Orchids.

DENDROBIUM ATROVIOLOACEUM, Rolfe, is a distinct and beautiful species allied to *D. macrophyllum*, better known in gardens as *D. Veitchianum*, though far superior as a garden plant. The sepals and petals are cream yellow, with numerous purple spots, and the labellum heavily marked with dark violet. It was imported from New Guinea by Messrs. James Veitch & Sons, and was awarded a botanical certificate on April 8th.—*Gardeners' Chronicle*, April 12th, p. 463; and April 26th, p. 512.

CYPRIPEDIUM X APOLLO, Measures. A hybrid raised in the collection of Mr. R. I. Measures, of Camberwell, from *C. Stonei* and *C. X vexillarium*, the latter being the pollen parent. It was exhibited on April 22d at a meeting of the Royal Horticultural Society.—*Gardeners' Chronicle*, April 26th, p. 526.

CALANTHE RUBENS, Ridley, is described as a charming novelty, allied to *C. vestita*, but with rose colored flowers. It was discovered by Mr. Curtis in the Langkawi Islands on the west coast of the Malayan Peninsula. Plants are said to have been sent to England.—*Gardeners' Chronicle*, May 10th, p. 576.

DENDROBIUM X VENUS, Rolfe, is a very beautiful hybrid

*Watson, *Proc. Am. Acad.* x, 339.—Watson & Coulter, "Gray's Man. Bot. N. S.," ed. 6, 36.

Fig. 49.—*Clematis Fremontii*.—See page 380.

raised in the collection of Mr. Norman C. Cookson from *D. Falconeri*, fertilized with the pollen of *D. Nobile*. It approaches *D. Falconeri* in character, though the yellow disc of that species is absent.—*Gardeners' Chronicle*, May 17th, p. 608.

BULBOPHYLLUM LEMNISCATOIDES, Rolfe, is a remarkable species allied to *B. lemniscatum* (*Botanical Magazine*, t. 5961), and like it having three remarkable appendages, one from the back of each sepal. It was introduced by M. van Lansberge, from Java.—*Gardeners' Chronicle*, May 31st, p. 672.

Kew.

R. A. Rolfe.

Moorea irrorata.—A few weeks ago, Mr. Moore, Curator of the Botanical Gardens at Glasnevin, Dublin, forwarded to Kew an inflorescence and leaves of an Orchid which he had purchased for a *Maxillaria* at an auction sale, but which differed so much from all Orchids known to him that he suspected it to be something quite new. This view was confirmed by Mr. Rolfe, who has described the plant under the above name. The leaves and pseudo-bulbs resemble those of *Houlletia* or *Xylobium*, the former being two feet long by four inches broad, and the latter four and a half inches long and tapering.

The spike springs from the base of the matured pseudo-bulb, and is nearly two feet long, erect, stout, with about a dozen flowers, each two inches in diameter, upon stalks one and a half inches long. The sepals are spreading, half an inch wide, chocolate colored, almost white at the base; the petals are similar, but narrower. The lip is three-lobed, side lobes rounded and thin, front lobe narrow and pointed. The color is bright yellow, with lines of black-purple; column cream-white. The plant is ornamental, and may be compared to some of the *Houlletias*. The generic name is so far unfortunate in that it resembles *Moræa*, an African genus of Irids.

Cultural Department.

Notes on American Plants.

THE Ragged Fringed Orchis, which flowers about this time, is not a very showy plant. The lower portion of the flower, which is known as the lip, is divided into many narrow thread-like segments. The flowers are borne in a loose spike about four inches long by a trifle more than an inch thick, and are of a greenish white color. It grows in moist meadows and pastures, also in thickets and bogs. It needs a moist place, and would thrive along the borders of artificial bogs.

Euphorbia corollata is a favorite plant with many who have grown it. Its height is from two to three feet, bearing its small white flowers in umbels. What appears to be the flower is only the five false lobes of the flower. These are white and very fine, the true flowers being inconspicuous. It is a hardy herbaceous perennial, and seems to thrive in any ordinary soil. Though not a troublesome plant, it soon forms strong clumps, spreading from the root.

A pretty Gentian from the Pacific coast is *Gentiana affinis*, but it varies much. The form now in bloom with us is hardly eight inches high, with blue funnel-shaped flowers over an inch in length and five-lobed. On the lower third of these lobes are numerous lighter spots, which add to the beauty of the flower. It seems to thrive well in this climate, but we cannot speak of its hardiness, because our plants were covered with leaves during last winter. A partly shaded location seems to suit it.

Dionæa muscipula, or Venus' Fly-trap, a native of sandy bogs in the Pine Barrens of North and South Carolina, is already too well known to need description. Its curious, sensitive leaves are its chief attraction, and these alone would well repay the trouble of growing it; but the white flowers, which, when grown in our northern climate, appear about the middle of July, are well worth having. It is not a difficult plant to grow if the right soil and situation are selected for it. Wherever a sandy bog can be made in open sunlight it will thrive. Even if this bog be confined to a common flower-pot the plant will thrive, if its natural home is closely copied. It needs protection from our cold winters, and six inches of leaves makes the best covering.

Rhexia Virginica (Deer Grass or Meadow Beauty) comes into bloom about the middle of July. The plant is seldom more than a foot high, bearing showy rose-purple flowers about an inch wide. The large yellow stamens add much to their beauty. It is a native of sandy swamps in Massachusetts, Pennsylvania, Wisconsin and southward. It needs moist, light soil in the sunlight.

Sedum Oreganum, a Stonecrop from the north-west, is quite an acquisition to a collection of this genus. Its thick, leathery leaves are small but very numerous, and have a purplish tinge, which, in a dense bed, give it a fine appearance. The flowers are yellow and in cymes, much resembling those of *S. ternatum* and *S. Nevii*, formerly mentioned, except in color. Of its hardiness we cannot yet speak, but it seems to like our summer climate and a light, loamy soil in the sun.

Perhaps the most variable of our native Lilies in size and the number of its flowers is the Wild Orange Red Lily (*L. Philadelphicum*). It is not rare to find in flower, in the same field, stalks varying from less than a foot in height, with a single diminutive blossom, to five feet high, with as many as six or eight large flowers. The proportion with more than two flowers to the plant is small, and most stems bear only one and two. But often the very small bulbs will send up a short stalk scarcely a foot high, which flowers. It is a native of dry, sandy soil, and when planted in a clay or clay loam does not seem to thrive at all, or, at least, I never have persuaded it to flower in such soil. But in a light loamy soil it is one of the easiest to grow.

During the summer months, almost everywhere, scattered over the bare summits of the higher mountains of northern New England and New York, may be seen in flower the little

Mountain Sandwort (*Arenaria Grœnlandica*). It is one of our prettiest little alpine, and not a difficult one to grow either by transplanting or from the seed. It is a little, low plant, forming dense tufts of its short, deep green leaves, and from among these, on slender, thread-like stems, scarcely three inches high, are borne the white flowers. These are a third or half of an inch wide. It needs a fine loamy soil, partly shaded, or it may be grown in gravelly soil in a cool place. It will thrive in shaded portions of the rockery. If grown from seed it must be in a fine, light soil, which will not become hard and which has no mixture of clay.

Monarda didyma, commonly called Oswego Tea or Bee Balm, grows much taller in cultivation than in its natural home. In rich garden soil it is frequently four and a half feet high, while two feet is about the height it attains in its wild state. It makes a pretty garden plant, the numerous large scarlet heads being quite conspicuous, and coming out in long succession. It needs full sunlight and ordinary culture.

Cimicifuga racemosa, commonly known as Black Snake-root, grows in rich woods from Maine to Wisconsin and southward. Its stems are from four to eight feet high, bearing at the top two or more long racemes of delicate white flowers. Most of the foliage is below the middle of the stalk. It is easy of culture in either sun or shade, and the long racemes are useful for cutting.

Allium reticulatum, from the western states, is a fine, large species. The stalks are often nearly two feet high, and each bears a large, round, many-flowered umbel of pale purple, or sometimes white, flowers. The flowers are very durable, lasting many days. It thrives in any ordinary soil in the shade, and is perfectly hardy in this climate.

Southwick, Mass.

F. H. Horsford.

Planting Conifers in August.

THERE is still a deeply-rooted prejudice against August planting. The comment is made, even by nurserymen and old planters, that it can be done, but that it is not practicable except on a limited scale and when the removals are for short distances. It is even said that it is misleading the public to advocate the practice. I need not now reiterate the theory of the comparative rest and maturity of the top of an Evergreen-tree after the middle of August, and, in contrast, the activity of the roots in the warm earth during September and October. It is most interesting to examine the roots of a tree late in the fall which had been moved two or three months previously, and to find how amply it is provided with feeders not only sufficient to sustain it against the exhaustion of the winter, but also to give it vigor for a strong start in the following spring. But, theory aside, I am impelled to state a few more facts in my own experience in addition to those heretofore presented (see GARDEN AND FOREST, vol. ii., p. 379), leaving them to have such weight as is due to them.

In the first week of September, 1889, I transplanted a lot of 326 *Picea pungens*, thirty-one Douglas Spruce and six Norway Spruce standing on a lot which I wished to clear and where the soil was considered too heavy for these varieties. The trees would run from two and a half to four feet in height. At the present date I find all the trees in most vigorous growth, with the exception of one *P. pungens*, which is dead. It is not the success in making them live which pleases me, it is the thrift of the trees, which, after an experience of forty years in transplanting, I do not hesitate to say, I never saw equaled in the first year of spring-planted trees. The same can be said of Austrian, Scotch and White Pines, Norway Spruce and *Retinosporas* transplanted last August. They have made better growth than I ever saw in spring planting.

But the objection is at once raised that all these were for short distances, and that "with special care Evergreen-trees may be moved short distances at any season of the year." Without stopping to show the inadequacy of the objection to meet the facts, I will cite other facts which seem to me to prove clearly that long distances may be successfully overcome. On the 15th of May, 1889, I received from a collector in Colorado 500 *Abies concolor* and 100 Junipers. On the 25th of the same month I received 400 *Picea pungens*. These came in such good condition and looked so promising that I ordered from the same collector in August, 1889, a much larger number. Upon this July 24th, 1890, I have personally examined and assisted in counting the two plantings and now submit the results.

Of the spring-planted 500 *A. concolor*, 190 are living; of the 100 Junipers 70 are living; of the 400 *P. pungens* 310 are living. The August collections were delayed in reaching me and were planted from September 9th until the 19th. Of the 2,800 *P. pungens* 2,332 are now living and 468 are dead. Of the 3,223

A. concolor 2,389 are living and 834 are dead. Of the 500 *Pseudotsuga taxifolia* 355 are living and 145 are dead. It may be thought that this is a large mortality, especially so with the Concolors and Douglas Firs. But, as these are all wild seedlings, a considerable shrinkage is to be expected.

Making the comparisons more definite it may be stated in round numbers as follows: Of spring-planted trees: sixty per cent. of *A. concolor* have died; thirty per cent. of Junipers have died; twenty-three per cent. of the *P. pungens* have died. Of fall-planted trees: twenty-five per cent. of *A. concolor*; twenty-nine per cent. of *P. taxifolia*, and twelve and one-half per cent. of *P. pungens* have died. The above seedlings were

ties are mentioned the average temperature necessary for their well-being will also be noted.

Though the members of this family in general are not specially particular in regard to soil, yet there are a few general rules to be observed—for instance, the soil should be coarse and open, to allow the water to pass through freely, and the pots or pans should invariably be well drained by means of a layer of potsherds, cinders or charcoal. A liberal supply of water should be given during the growing season, and after the plants become somewhat pot-bound an occasional watering with liquid manure will have a good effect, providing it be not used too strong. During the winter somewhat less water will

View in the Sihlwald.—See page 386.

of various sizes, from six to ten inches in height. I wish to add, in fairness, that I received from another Colorado collector September 19th, 1889, 1,000 *P. pungens* of a larger size, from one to two feet in height. As might be expected they were more stunted and unpromising. The mortality has been heavy upon this lot, rising above fifty per cent., or, stated more exactly, 527 are dead and 473 alive at this date. For myself I shall continue to advocate the planting of conifers in August and September. For long distances, it is only necessary to guard against heating and drying. Success presupposes care.

Waban Nursery, Newton Highlands, Mass.

Wm. C. Strong.

A Few Strong-growing Adiantums.

THE extensive Maiden-hair family presents much diversity in sizes and forms among its many species, all of which are beautiful, and many of them notably so. It is not intended, however, in this connection to present a catalogue of species, but to invite attention to a few of the stronger growing sorts, many of which flourish under cool-house treatment, or in an ordinary conservatory temperature. Of course all strong-growing Adiantums are not greenhouse sorts, as some of them do much better in a warm-house, but where such varie-

ties are mentioned the average temperature necessary for their well-being will also be noted.

Among the older species, *A. trapeziforme* occupies a prominent place, and is surpassed by few when well grown. It is easy to manage and makes a shapely plant, the leaf-stems being so stiff that they seldom need staking. Its fronds attain a height of from three to four feet, the pinnæ being very large, light green in color and trapezoid in outline. *A. trapeziforme* is of West Indian origin, and has been in cultivation for many years.

A. formosum is another species of special elegance and utility, and is well adapted for cool-house treatment. Its quadripinnate fronds sometimes reach a height of four feet, though they are more often seen two or three feet in height. The pinnæ are much smaller than those of the preceding sort, and the fronds are somewhat stiffer, and are produced from very free-growing rhizomes, the latter being often found coiled around the interior of the pot from top to bottom. It is a native of New Zealand.

A. Peruvianum is an excellent sort of more recent introduction than the above, and, as its name indicates, was first found in Peru. It has long fronds of gracefully arched habit, clothed with very large pinnules of bright, light green, and will make satisfactory progress in a warm house, where its growth in a tem-

perature of sixty to sixty-five degrees will be rapid and strong.

Of course no collection of Ferns is complete without the "Queen of the Maiden-hairs" (*A. Farleyense*), at least no collection that includes warm-house species. This lovely Fern is becoming so widely known that a description seems unnecessary, and for that matter, written description almost invariably fails to do it justice. Suffice it to say that it well deserves the title of Queen, being unrivaled in delicacy, grace and refinement. The origin of *A. Farleyense* has been rather doubtful, though it seems clear that it was first introduced from Barbadoes, and the opinion has been expressed by those qualified to judge, that it really is a cristate form of *A. tenerum*, and it is claimed that seedlings from *A. Farleyense* have reverted to the original type. I have never seen such seedlings; in fact, I can only recollect seeing a fertile frond on *A. Farleyense* on one occasion.

A. Sanctæ Catherinæ is also to be recommended among the strong growers. It is a native of Brazil, and bears some resemblance to *A. trapeziforme*, though rather more compact in growth than the latter, and its young fronds are more noticeable on account of their pleasing bronzy pink tint. When mature its fronds are dark green in color, with shiny black stems, and they average about two feet in height.

A. tenerum is also a desirable species, and seems to be quite widely distributed. It is an evergreen warm-house species, and produces graceful light green fronds from two to four feet in length. The smaller fronds are also valuable for cutting, as they last well in water.

A. cardiochlamæ, otherwise known as *A. polyphyllum*, is one of the finest of all when grown as a large specimen, and like most of the large-growing Adiantums it requires plenty of pot-room to develop its full beauty, and also an abundant supply of water at the root. It was introduced from South America a number of years ago, but does not seem to have become very common. It has upright foot-stalks, but drooping fronds, which are of a pleasing light green color, and usually three times divided. These fronds have been known to reach a height of six feet, though this is unusual, and the average is probably from two to three feet.

A. villosum is another fine species from tropical America, and though considered a warm-house plant, may be readily grown in a temperature of fifty-five degrees. It has dark green, bipinnate, glossy fronds about two feet in height, the stems of which are covered with short brown hairs.

Holmesburg, Pa.

W. H. Taplin.

Rose Notes.

Madame Georges Bruant.—This fine Rose will soon find its way into every good collection. It came through the past two winters in fine style, though many varieties considered absolutely iron-clad have succumbed to the trying extremes of temperature. How it will endure the test of twenty degrees below zero remains to be proved. When its clusters of immense dazzling white flowers open against its profusion of dark foliage it is lovely to behold, and its odor is exquisite. The open rose is very beautiful though only semi-double, for its texture is like satin and its color like driven snow. It seems a pity to note the weak points of a Rose so nearly perfect, but (1) it is liable to mildew when there are very marked changes between the night and day temperature, though not so weak as La France in this respect; and (2) the long, delicately pointed buds are apt to brown on the tips if met by heavy rains followed by a hot sun. It might be called a "Monthly Rose," so regularly does it bloom at intervals during the summer.

Gloire Lyonnaise is one of the very finest of the white Hybrid Perpetuals; not a whit behind the aristocratic Merveille de Lyon or White Baroness, while in most situations it proves a hardier and more satisfactory grower than either. The bloom is a rich creamy white, a tint found in no other Rose of its class. It is a beautiful upright grower, with the soft, leather-like foliage of the strong growing Teas. The open flower is very sumptuous in appearance, very lightly scented, but destined to become our most widely grown white Hybrid Perpetual. In common with all hardy Roses, its beauty is liable to be despoiled just as it comes into leaf by the Rose pest; but one or two good doses of hellebore will prevent this, and we have only ourselves to blame if leafless branches or skeletonized foliage meet the eye.

Madame Plantier is an old favorite, which, though small of flower and fine of foliage, should be found in every garden. There are many uses for which this small, perfect white Rose is especially adapted. It comes safely through all kinds of weather and seldom fails to bring a lavish profusion of lovely flowers.

Polyantha Mignonette must become better known. A row forty feet long planted six years ago was a sight to be remembered as it came into a mass of bloom the last of May. To the uninitiated it was a puzzle; it was guessed to be everything but a Rose, until a very close examination of the foliage settled the question. Rosy pink and white were the great armfuls of fairy roses, the single flowers an inch in diameter and in clusters of forty and fifty. It blooms very perfectly until hot weather sets in, when the roses blight in the bud unless a good part of each cluster is pruned away. We may safely look to this section for some splendid acquisitions for the hardy Rose bed.

The Moss Roses were, many of them, a disappointment, as they all showed a tendency to open in a one-sided fashion and without apparent cause, except our grand old friend *Cristata*, which was in superb condition. The long buds of heavy green moss opened slowly and perfectly to show a splendid double rose of brightest pink, with that peculiar odor which, once inhaled, can never be forgotten.

It seems a great pity that many of the best Mosses, some of the finest Hybrid Perpetuals and the Austrian Roses should be of such difficult propagation as to make it next to impossible to secure them on their own roots. Perhaps the florist of the future will find a means of rooting them more readily, when we may hope to find them more generally distributed through American gardens; for the American amateur insists on having "own-root" plants, and, generally speaking, he is right, for it is a fact that many grafted plants, that should have been in their prime in 1890, were weakened by the freezings and thawings of the winter of 1888-1889, to be killed outright by the severe cold of the past March following a warm February.

Richmond, Ind.

E. G. Hill.

The Brazilian Miltonias.

THE Brazilian species of *Miltonia* are not so generally grown in amateur collections as their beauty warrants. Nevertheless they are very desirable, growing freely and always flowering well under proper care. They have the good quality, too, of flowering at a dull time of year, usually during the months of August, September and October, when their large, conspicuous flowers are very attractive, and they remain in good condition for several weeks. These *Miltonias* can be grown in a shady corner of the Cattleya-house, where it is possible to shade them at all times from the direct sunlight. They should be grown in pots filled to within two inches of the rim with broken potsherds, over which is placed a layer of fresh sphagnum to keep the potting material from the drainage. Equal parts of peat and live sphagnum moss suit them admirably. Care must be taken to elevate them well above the pot and not to bury the rhizome. While growing they require a constant supply of water, and at no time of the year must they be allowed to get dry. Syringing overhead morning and evening is beneficial to them while growing. The following species are those most generally found in cultivation and usually prove the easiest to manage:

M. cuneata, with flowers borne on spikes, several together; the sepals and petals a rather dark shade of brown tipped with pale yellow, the lip white.

M. candida, a very pretty species, bearing many brown, yellow and white flowers on each spike, one of the strongest growers of the genus. Its variety, *Grandiflora*, is a decided improvement, having larger and much brighter flowers.

M. Clowesii, var. *major*, another strong grower producing long spikes freely, with flowers of good size. The sepals and petals are primrose yellow, the ends of which are barred with rich brown; the lip is white, suffused with purple.

M. Morelliana, and its variety *Atrorubens*, decidedly pretty plants, not so tall as those named above, but having larger and more attractive flowers. *M. Morelliana* has sepals and petals of rich, rosy purple, while the very broad lip is pale rose with veins of a deeper hue. The variety *Atrorubens* is much richer in color in all parts, but is rather a rare plant.

M. Regnellii, with flowers on long spikes, sepals and petals milk white, with a rosy colored lip. There is a distinct and superior variety, *Purpurea*, with sepals and petals rosy white, and the lip a splendid purplish crimson.

M. spectabilis, small, but with extra large flowers, having sepals and petals pure white and the broad lip pale rosy white, streaked with violet-purple. This is perhaps the most variable of the Brazilian *Miltonias*, and one of the best.

Many growers grow *M. spectabilis*, and *M. Morelliana*, which is really one of its varieties, on blocks of Tree Fern placed in pots, but they rarely do as well when their small, wiry roots are exposed to atmospheric changes and especially to dry air.

Easton, Pa.

Herbaceous Pæonies.

THE flowering season just over has been one of the best I remember for Pæonies. A large bed of named varieties was a fine sight for the two or three weeks during which it was at its best. These plants revel in well manured soil, and, although they are impatient of removal, the manure may be lightly dug in without causing them any injury. If it is wished to move or divide any established plants, it should be borne in mind that they will not flower satisfactorily the first year after removal, but with generous treatment this will be the extent of the loss. Care should be taken in the selection of sorts, only the most robust being suitable for growing in prominent positions. There are some kinds which appear to have a tendency to develop a great number of small crowns that are useless for flowering, and these are very disappointing, for it seems almost impossible to induce them to make really satisfactory growth, and, at most, one or two flowers on a plant are all they will produce. All such kinds are ineffective in a flower-garden. The old *P. officinalis* is very useful for planting in rough places amongst the Grass or as a fringe to the shrubbery, for it does remarkably well when let alone after it gets established. None of the named kinds I have seen can compare with it for this sort of work.

I append a list, selected from about thirty named sorts, which have been exceptionally good here the past season:

Candidissima.—Pure white guard-petals, pale primrose centre.
Carnea grandiflora.—Delicate blush, changing to pure white, incurved flower, very strong and good.

Charles Binder.—Deep rose, very full flower, scented.

Constance Devred.—Deep carmine, large flowers.

Dr. Calot.—Deep rose guard-petals, centre salmon.

Festiva maxima.—Pure white, incurved, stained carmine on centre petals, strong grower, magnificent.

Isabella Karlitzky.—Carmine-rose, full centre, very fine, scented.

Louis van Houtte.—Bright, purple-lake, strong grower, very large flowers, Hawthorn scented.

Marie Dhour.—Pale flesh color, full centre, dwarf, fine and free, scented.

Mme. Muysaert.—Bright rose, light centre.

Mme. Jules Calot.—Bright rose, chamois-yellow centre, scented.

Paul Rubourg.—Rose, very double, late, strong and good.

Rosamond.—Rose, incurved, strong grower, very fine flower, scented.

Rubra triumphans.—Deep crimson, incurved, strong grower.

Whitleyi.—Single, pure white, large ball of golden anthers, dwarf, free, and the earliest of the section.

J. C. Tallack, in *The Garden*.

Disa tripetaloides is a beautiful little species which has lately attracted much attention and even admiration from members of the Orchid-loving community, and it is probable that it will soon become tolerably well known, for it has features which will readily recommend it, viz.: the ease with which it may be grown, the length of time its flowers remain in perfection, and their quiet and charming character—so different from that of the *Grandiflora* section. Flowering specimens have been exhibited during May and June in London. The leaves are lanceolate-acute, deep glossy green, somewhat fleshy in texture, three to four inches long and about half an inch broad in the widest portion. They are clustered at the base, but pass up the scape, which springs from the centre alternately, and change into green bracts. The erect scape is from nine inches to a foot high, and bears as many as twenty to thirty flowers, each of which is about three-quarters of an inch across, and of a beautifully soft, very pale lilac, handsomely speckled with deep rose. The upper sepal reminds one of a monk's cowl with a short, conical spur at the back. The lateral sepals are, in comparison, much larger, elliptic-oblong, while the small falcate petals and linear lip are within the precincts of the upper sepal and require close inspection to make them distinguishable.

This species, although now brought prominently before the public, is by no means new, having, according to Mr. N. E. Brown, of the Kew Herbarium, been discovered over a hundred years ago in South Africa by the traveler Thunberg, and named *Orchis tripetaloides* by the younger Linnæus. Thunberg afterward confused it with his own *D. excelsa*, and Dr. Lindley thought it to be *D. venosa* of Swartz, a plant whose identity has been mixed up with *D. racemosa*. To make matters clear Mr. Brown therefore retained the specific name given by Linnæus the younger, and re-named it *Disa tripetaloides*.

Those who are in the habit of looking at every Orchid as requiring "heat and moisture" will perhaps be agreeably sur-

prised to learn that the subject of this note is a cool-growing and even hardy species. Mr. James O'Brien, of Harrow-on-the-Hill, to whom its re-introduction to cultivation is due, has grown his plants in pans in a cold frame, where they have freely flowered—some of them having even been subjected to frost. It is evident from these facts that *Disa tripetaloides* should grow well in a cool house, without requiring so much attention as some of its larger flowered congeners.

London.

John Weathers.

Kniphofia (Tritoma) Saundersii.—One of the most pleasing and brightest things in the garden lately has been this beautiful Torch Flower. With its deep green, angular, rush-like foliage, and massive stems surmounted by the long spike of brilliant flowers, this is one of the most noble of plants. A well grown clump would be an attraction in the best of gardens. The flowers of this variety are a very pleasing orange-red, shading into orange. They are individually of good size, the spike being a foot or more long. Unfortunately, the plant is not entirely hardy here, needing careful protection from frost and wet, but well worth any amount of trouble.

Chrysanthemum maximum.—A trade circular just received, in which this is included as a choice perennial, leads me to say that it is a weed, or, in other words, a plant not worth a place in the garden. For three years I have been trying it without discovering other merits than its neat, vigorous habit. The flowers, under ordinary cultivation, are little larger than those of a well grown field Daisy, but perhaps if well fertilized they might be half an inch broader. The white Daisies are beautiful in the meadows, but, with their present abundance, it does not seem worth while even to give a slightly better variety room in the garden. Fortunately, *C. maximum* does not seem as hardy as the common White Weed. Some few years ago some seed from Vilmorin produced flowers with a tendency to doubling, and I notice a similar variety offered as *C. semi-duplex*. It is perhaps unnecessary to say that such flowers are abominations. If White Daisies of good size are desired early in the year, it would seem that the single Hybrid Pyrethrums are altogether the most useful and handsomest, both in flower and foliage. In a good strain of mixed seed some fine white ones will usually be found as well as the ordinary reds.

Plant Notes.

Papaver Californicum.

THIS true Poppy, the only one indigenous to California, was discovered in 1886 in the Santa Inez Mountains by Mr. John Spence, of Santa Barbara. It was described by Dr. Asa Gray in the *Proceedings of the American Academy of Arts and Sciences*, vol. xxii., pp. 313-314, thus being one of the last California flowers to receive a name at the hands of that illustrious botanist. Not only is it one of the latest discoveries, but it justly ranks among the handsomest of the annuals of the Pacific coast.

It is rarely found except on ground which has been burnt over, Mr. Spence first finding it far away from any cultivated fields at an elevation of 1,500 to 2,000 feet, on ground which had been covered principally with Manzanita bushes, but had been burned over the year before. Probably for this reason, and from its close resemblance in appearance to *Meconopsis heterophylla*, a less showy plant, but with flowers almost identical in size and coloring, it owes its escape from previous discovery.

As Dr. Gray suspected, this is not a local species, but is apparently widely distributed in southern California, having recently been collected by several botanists in widely separated localities, but everywhere under similar conditions as first found—on tracts of burnt brush-lands at from one to two thousand feet elevation. This spring I observed it in great abundance back of San Diego, near Potrero, and also between the Cajon and Santa Maria valleys, on hill-sides burned over by forest or brush fires last fall. Although I have traversed both sections repeatedly during the past ten years this richly colored flower had never been seen before these fires had denuded the land.

It forms a fine, bushy plant about a foot in height and bears a profusion of large, showy flowers of an average of two inches in diameter. The color of the large, delicate petals is a bright, saturn red to orange chrome, with a centre of a delicate sulphur yellow. In cultivation it is said to make a fine pot-plant, and if it improves as most of our wild flowers do under the attention of horticulturists, it will prove a most desirable addition to American gardens.

Associated with it is usually found *Phacelia Orcuttiana*, another so-called "fire weed" which is likely to prove a welcome acquisition to the garden on account of its masses of white flowers with conspicuous yellow centres. This *Phacelia* grows into a tall, stately plant, branching freely from the base.

It is an interesting problem why the seeds of these handsome plants should lie dormant so many years in the soil, awaiting the—to them—life-saving, destructive fire. After once starting into existence the seed does not seem to require to pass through the ordeal of fire before growing, for the second year after a fire they appear in greater abundance than the first. Gradually, however, as other plants get re-established on the ground these become fewer and fewer, until other vegetation overcomes them, and their seeds again lie dormant in the soil awaiting another deluge of flame.

San Diego, Cal.

C. R. Orcutt.

CLEMATIS MONTANA.—A charming picture of a porch covered with this climber, in a recent issue of *The Garden*, of London, reminds us that the plant, although very rarely seen in gardens in this country, is perfectly hardy here, and that it is one of the very best of the early-blooming vines. Splendid shoots wreathed with the clusters of large white flowers were shown a month ago at one of the weekly exhibitions of the Massachusetts Horticultural Society by Mr. Joseph Clark, gardener of Henry L. Higginson, of Manchester, Massachusetts. *Clematis montana* is a native of Nepal, whence it was introduced into English gardens as long ago as 1831. It is a rampant grower, producing, if the plant is severely pruned immediately after it has done flowering, shoots sometimes six or eight feet long, which flower the following year from end to end. As the writer in *The Garden* says, "its early blooming character, fitness for all ordinary soils, and complete hardiness, save in very cold spots, have raised it to the position it holds in the garden. It must be a poor place that has not rambling over a veranda, trellis, arch or wall *Clematis montana*." The specimen forming the subject of *The Garden* illustration has been planted for over thirty years in its present position, blooming freely every year, and covering the whole front of a house. It is planted in a border close to the wall and obtains little surface water. It is cut back once or twice a year.

The Forest.

The Sihlwald.—II.

IN the organization of a normally stocked forest the object of first importance is the cutting each year of an amount of timber equal to the total annual increase over the whole area, and no more. If is further desirable in any long settled community that the forests be so managed as to yield a measurably constant return in material. Otherwise difficulties in the supply of labor and the disposal of the produce make themselves felt, and the value of the forest to its owner tends to decrease. This is especially true in the case of the Sihlwald, whose mills derive their raw material exclusively from the forest to which they belong, and whose supply of labor is limited to the men whom it furnishes with steady employment. Either excess or deficit in the annual production implies loss.

In order to attain this steadiness of yield it is obviously necessary that a certain number of trees become fit to cut each year. The Sihlwald has accordingly been so "organized" that areas of equal productive capacity are covered by stocks of every age, from last year's seedling to the mature tree. These age-gradations succeed each other in a series so regular that in an hour's walk one may pass from the lot just cut over through a forest of steadily increasing age to the trees which have reached the limit of the rotation of ninety years. Three such units of organization are present in the Sihlwald, but since the character of the Fraumunsterforst, as the forest on the right bank of the Sihl is called, separates it distinctly from the much greater area of the Sihlwald proper, and since the two divisions of this last differ only in unessential matters over which the treatment has no control, it will be necessary to speak of only one of them. The working plan for the Lower Sihlwald, then, prescribes for the forest which it controls the operations of what Dr. Schlich has called in his *Manual of Forestry* "The Shelter-wood Compartment System." It may not be without interest to follow the life history of a compartment in which this system is carried out.

After the mature trees had been felled and removed from the area which furnished the yield of the Lower Sihlwald last year the thick crop of seedlings which had grown up under their shelter was finally exposed to the full influence of the light and air. The felling and rough shaping of the timber,

the piling of logs and cord-wood and the trampling of the men had combined with the crisis of exposure to destroy the new crop in places and create a few small blanks. Here, as soon as the disappearance of the snow had made it possible, groups of the kinds of seedlings necessary to preserve the mixture or destined to increase the proportion of the more valuable species were planted. The operation, necessarily an expensive one, is justified by the greater resistance of a mixed forest to nearly all the calamities which may befall standing timber. Simultaneously with the planting the Willows, Hazels and other worthless species were destroyed, as well as the "pre-existing seedlings," whose larger growth, according to the disputed theory held at the Sihlwald, would damage their younger neighbors more by their shade than their greater volume would increase the final yield of timber. The incipient forest, then, practically uniform in age and size and broken by no blanks which the growth of a year or two will not conceal, is fairly started on the course of healthy development, which it is to continue undisturbed until it reaches the age of fifteen years.

At this point occurs the first of a series of thinnings which follow each other at intervals of seven or eight years, until the trees have entered the last third of their existence. There is, perhaps, no silvicultural question more in dispute than this of the time and degree of thinning which will yield the best results in quality and quantity of timber. The method pursued at the Sihlwald, consecrated by habit and success, gives ample space for the healthy development of the crown from a very early age without admitting light enough through the leaf-canopy to sustain an undergrowth until the trees are nearly ready to give place to their descendants. Such shrubs or seedlings as still appear, thanks to a shade-bearing temperament, are systematically cut out. It may be strongly doubted whether such a policy might safely be applied on soil less moist than that of the Sihlwald; but here, at least, the trees reach the age of sixty years, tall, straight, clean-boled, and in condition to make the best of the last part of the period of maximum growth, which a large number of measurements have shown to occur in general between the ages of seventy and ninety years. A heavy thinning now comes to the assistance of the best specimens of growth, and they are left to profit by it until seven years before the date fixed for their fall. Then begin the regeneration cuttings, whose object is to admit through the leaf-canopy an amount of light, varying with the temperament of each species, whose mission is to give vitality to the seedlings which the trees, stimulated themselves by their more favorable situation, now begin to produce in considerable quantities. To this end the light which falls from above has a powerful auxiliary in that which the system of felling each year in a long, narrow strip admits from the side, and so admirable is this double method that the time which elapses between the beginning and the end of a regeneration is but half the average for less favored localities. This applies only to the deciduous trees. The time required by the conifers is much longer, and the incomplete regeneration which they furnish is supplemented by planting in the blanks already mentioned. But for the self-sown seedlings of both classes the amount of light is gradually increased, the trees which sheltered them are at length wholly removed, and the cycle of growth repeats itself.

The wagon roads which once served for the transportation of the timber thus produced, although admirable in plan and construction and still thoroughly maintained, have been almost wholly superseded by a system of timber slides and narrow gauge railroads, in which gravity is the motive power. The timber, loaded directly on the cars of the light, portable track laid in the forest (see page 383), or, where the surface is broken, hauled to them by tough little Swiss oxen or carried down on hand sleds which are capable of taking enormous loads, is delivered at the head of one of the slides. Thrown in at the top of the V or U-shaped canal of boards or poles, it rushes down the steep incline of the slide with a speed which often shoots the sticks of cord-wood through the air for a distance of one hundred and fifty feet as they rebound from the iron-clad platform at the foot, and not infrequently tears apart great logs in the violence of the fall. Piled once more on the cars, this time of one of the two permanent tracks which follow the bottom of the valley at divergent levels, the timber pursues more quietly its journey to the mill, whither it arrives in trains of from five to twenty cars under the guidance of a single brakeman. Such a system of transportation is only possible where considerable amounts of timber are cut on limited areas, but its application to the Sihlwald has resulted in so steady and marked a decrease in the cost of moving the produce of the forest to the mills that its value under similar circumstances may be taken to be proved.

Our Schools and Gardening.

To the Editor of GARDEN AND FOREST:

Sir.—I have lately had occasion to discuss elsewhere the subject of our common school education as bearing on rural life, horticulture and farming. This was recalled to me by an editorial recently in GARDEN AND FOREST on horticultural education. Agricultural colleges are of value in their way; but they are too far along and their influence is exercised too late. A boy, graduate of our common schools and sent to an agricultural college, goes charged with a popular bias in favor of trade. It is a simple fact that commerce in any form is held to be honorable, but land-tillage is looked down upon. My friend Parker can retail my potatoes, peas and berries, but the raiser of vegetables and berries for market, and the first sale of the same, brands one as belonging to a lower caste. It needs considerable decision to get on a load of cabbages and take them to market. Now, I have learned to trace this error in public judgment to a foundation or causal error in education. The trouble in this case is that our schools are in no sense whatever adjusted to farm life and farm work. "Any one can be a farmer. It needs no special education to grow onions." This is the public sentiment that must be corrected, and with it the false methods of study. There will be no demand for higher education in horticulture or agriculture until pupils are started in the right direction in the common schools.

A man who sends his boy to school with the direct purpose of qualifying him to comprehend and love the things which come under his eye and other senses, and in order to enable him to enter into sympathy with his work in the field, will be disappointed. The horticulturist needs to understand vegetable and animal life—their history and evolution, the possibilities involved in climatic and other environments—and should be prepared for the comparative and experimental cultivation of plants, trees and animals. Will the curriculum of the common school prepare the boy or the girl in these directions? Out of this they get neither botany nor zoology; neither horticulture nor gardening in the narrower sense; neither a knowledge of soils, nor of rocks, nor of vegetable chemistry. What is given to the child is more specifically that which inclines him to trade, and away from land culture. It will not do to rely on a higher training after the bias is given. The suggestive plan proposed by GARDEN AND FOREST and by Professor Bailey, covers the advanced need of a pupil already under way with elementary biology. But until our schools specifically recognize, from the outset, the dignity of gardening and field work, education will unfit, rather than fit, us for being an agricultural people.

I am persistent in beginning with all my children at a knowledge of soils and rocks, the land under their feet, and its make-up geologically. Then I pass on to the life on the earth—vegetable and animal. So long as I can find an elementary book like that of Professor Shaler there is no trouble with geology. As for zoology and botany we are also fairly well supplied with good books. Chemistry in laboratory work follows. And so the lads from ten to twelve years of age have a knowledge first of all of the world about them and the life on it. It is mostly field work and laboratory work; and with it goes drawing, from the outset. Such a course gives them a passion for the soil and plants and animals, from the beginning of their mental development. I may add that they never think of such studies as tasks, but as enthusiasms. I do not advocate directing a boy to land culture when he has a marked taste for machinery or for literature; but the retention by wise and fitting education of those who naturally should be farmers and gardeners.

Clinton, N. Y.

E. P. Powell.

Bermuda Grass.

To the Editor of GARDEN AND FOREST:

Sir.—The grass on the lawn of your correspondent at Frankfort, Kentucky, "making a growth all through June," is doubtless the Bermuda Grass (*Cynodon Dactylon*), as you have determined it; but it is not usual to find it troublesome where other lawn grasses will grow, and this experience with it in Frankfort is very interesting. The foliage of this grass is so easily killed by frost that it does not seem able to gain a foothold north of the Potomac. Botanical works give its range as from Pennsylvania southwardly; but I have never been able to find a specimen except in the ballast ground near Philadelphia, where it occasionally springs up from the seeds brought in the ballast, but does not spread beyond. In the admirable list of the "Flora of New Jersey," from the pen of Dr. Britton,

just published as part of the work of the Geological Survey, it is noted only in a few instances on wharves or in ballast heaps.

That it rarely seeds in the United States is, I think, a popular error. It flowers rather early, and before its later creeping habit begins. In that state it attracts popular attention, and there no seed vessels are seen. Years ago, when examining the horticulture and agriculture of Louisiana and Mississippi, Colonel Hillyard, now of New Orleans, remarked to me on one occasion near New Orleans, "They say this never seeds. Look, it is abundantly seeding here." Again, some years later, I was crossing the then unfinished grounds in front of the new National Museum at Washington with Professor Porter, of Easton, who called my attention to the abundant fruiting of the grass on that waste ground. A specimen that I gathered there I subsequently sent to Doctor Thurber, who had given currency to the non-seeding reputation of the Grass.

The "dwarfed, late-starting Grass of the northern states, so destructive to northern lawns" (page 363) is probably *Panicum sanguinale*.

Germantown, Pa.

Thomas Meehan.

Recent Publications.

Les Champignons, Traité élémentaire et pratique de Mycologie suivi de la Description des Espèces utiles, dangereuses, remarquables. Par J. Moyen avec une Introduction par Jules De Seynes. Paris: J. Rothschild. Pp. xxxv., 762, 20 chromolithographs and 334 wood-cuts.

The French certainly understand the art of making popular treatises on natural history. To artistic skill in the production of plates they generally add a style which, although approaching diffuseness, is clear and easily followed. The present work, in spite of its 800 pages, is so well arranged that the reader can easily find what he wants to know and read it quickly. It is one of a class of books of which a considerable number have appeared in the last few years whose object is to give to the unscientific, or mildly scientific, reader a general view of the forms and properties of all kinds of fungi and a more detailed knowledge of the species which are edible or poisonous. It contains a large amount of information, and we do not know any better elementary work of the same scope. The numerous wood-cuts are a great help to the beginner who wishes to study the subject from a botanical point of view, and the amateur who is only in search of some ready means of recognizing the principal edible and poisonous forms will find the colored plates a practical aid. The larger part of the text is devoted to a "Flore Mycologique," or description of the most important *Basidiomycetes* and the larger *Ascomycetes*, followed by an artificial key to the species and a glossary of technical terms. The medical man would perhaps prefer the work of L. M. Gautier, *Les Champignons*, and the expert mycologist would require more technical works, but the present book is to be recommended to those general readers and amateurs who desire to begin the study of fungi, for it offers in a condensed and simple form the substance of a good many books. The reader may perhaps feel that too much is given, but that error, if it be an error, is one easily pardoned.

Notes.

California nectarines are in the market, and very good they are. Some of the California peaches, too, are fair, and there are few others to be had in the city. Jamaica oranges are just coming.

In an article on the "Botanic Gardens at Kew," recently published in the *Popular Science Monthly*, it is said that between six and seven hundred thousand persons visit them in the course of a year.

It is reported in the *American Agriculturist* that a rust has appeared on the Canada Thistle. The fungus spreads rapidly and is very destructive of the host plant, which is well known as one of the most pestilent of weeds.

We are advised that Hill & Co., proprietors of the Rose Nursery at Richmond, Indiana, have retired from the retail business. Hereafter the Messrs. Hill, in a new location not far from the city, will limit themselves to a wholesale and novelty trade.

Clethra barbinervis, obtained from Japan through Mr. Thomas Hogg in 1875, is now in bloom at the Kissena Nurseries, Flushing, and a very striking shrub it is. It is a strong grower, with leaves six and a half inches long and three inches wide on leaf stems one inch long. The flowers are pure waxy white, with white pistil and stamens, and they are arranged in racemes six

inches long. The plant is specially valuable because it blooms when few shrubs are in flower. Mr. Parsons reports that it is sometimes affected slightly by the winter.

The proceedings at the fifteenth annual meeting of the American Association of Nurserymen, held in this city last June, have been promptly published in a neat volume of 100 pages, with a portrait of the President for the coming year, Hon. S. M. Emery, of Minnesota.

An exhibition of jams, bottled, preserved and dried fruits of all kinds, is to be held in London under the direction of the Royal Horticultural Society, on the 14th, 15th and 16th days of October next. The chief object of the exhibition will be to show the advance which has been made during recent years in processes of preserving and drying edible fruits for consumption. For the schedule of premiums and other information application should be made to the Secretary of the Royal Horticultural Society, 117 Victoria Street, London, S. W.

The American Forestry Association has accepted the kind invitation of the Government of the Province of Quebec to hold its annual meeting in the Parliament Buildings, Quebec, from the 2d to the 5th day of September. While the conditions under which the Association will meet are a guarantee for earnest and useful work in the cause of forestry, the historical city of Quebec, with its beautiful surroundings, will also help to secure a large attendance. All persons who intend to read papers at the meeting are requested to send the title to the First Vice-President, Honorable H. G. Joly, 15 Buade Street, Quebec, before the 15th of August.

Captain Hayward is the name of another finely colored and scented new Hybrid Perpetual Rose, sent out by Mr. Henry Bennett, of Shepperton, and a correspondent of *The (London) Garden* speaks of it as a valuable addition to a long list of good things this raiser has produced. The flowers are very showy, and remind one when fully expanded of those of Ulrich Brunner, but they are quite distinct. Their color is rich crimson, shaded with a bluish tone when open, while the scent is strong and rich. The vigor of the bloom and stem indicates unusual robustness in the plant, and if this proves true then we have a welcome Rose of fine, bold character for the garden.

Different *Kœlreuteria*-trees vary considerably in their time of coming into bloom. This year we observed one in full flower on the fourth of July and near it is another which is still in flower. The trees vary greatly also in the appearance of their fruit, which stands out above the foliage in large spreading, bladdery panicles. In some the color is a very soft, light yellowish green, while in others even at their earliest appearance the color is a rich reddish bronze. The *Kœlreuteria* is one of the most interesting of small trees at all seasons. Its foliage is abundant and healthy, and rarely visited by destructive insects. The great panicles of bright yellow flowers make it a striking object when in bloom, and the fruit, until it dries up and turns brown, also adds to its effectiveness.

The carelessness with which writers in popular journals speak of trees was shown in a recent number of the *Pall Mall Gazette*, when the fabled "World-tree," believed in by northern nations in Pagan times, is spoken of. New Yorkers have had a picture of this "World-tree" put before them of late in Wagner's opera, where Siegmund draws from its giant trunk the enchanted sword, and many will recollect that in the text it is called an Ash—*Esche*. Such in fact it was thought to be, and it is well known that the Ash, like the Oak, long retained its sacred character among the Germans even after they were christianized. Yet the writer referred to calls the "World-tree" a "Mountain Ash." This does not mean an Ash at all, as every one should know, for the tree is common everywhere in cultivation, but a tree of another family altogether, one which never grows to large dimensions and belongs in the same genus with the Apple and Pear.

The people of Florida believe that there is a prosperous future for the Pomelo as a summer fruit. This fruit varies in acidity. In most varieties the acid becomes agreeably mild in May, but in many instances it remains strong until midsummer, so that by proper selection and management good fruit can undoubtedly be had all through the hot season. In the middle of July some fine fruit appeared in the Jacksonville market and sold there at ten cents apiece. The *Lakeland Advocate* quotes returns for seven boxes of bright Grape-Fruit in good condition, each box about the size of an ordinary orange-box and holding some fifty fruits, and they netted the grower more than eight cents apiece. This is said to be the highest wholesale price yet received, but certainly it is not more than the real value of the fruit, which many people

consider superior to the orange. It should be eaten so as to avoid the bitter flavor of the peel and the core, the best method of preparing it being to peel the fruit first and then carefully to separate the pulp from the remaining integuments.

Quoting from an Italian journal a writer in the *Bulletin of the Torrey Botanical Club* for July says with regard to the naturalization of American plants in France: "In 1881 on the banks of the Meurthe, near Nancy, a few specimens of *Lepidium Virginicum* (Wild Peppergrass) were found among growths of *Lepidium ruderale* (a European species which is sparingly adventive in this country), and two other adventive American plants, a *Gilia* and *Amsinckia lycopsioides*. They lasted about ten years and disappeared along with the manufactory of flannel shirts, to which they probably owed their origin in that place, as the wool used in the looms (presumably brought from Chili) was cleaned in the river and spread on its pebbly banks to dry. *Lepidium Virginicum* disappeared with the rest of the foreigners, but several years later was found again near Nancy, and, with *Poa pœooides* and *Salvia verticillata*, is spreading along the railroads. *Oenothera biennis* and *O. muricata* are adventive on the banks of the Moselle and abundant there," while the same Peppergrass, which has been so persistent at Nancy, has been known for forty years in one spot at Bayonne, and has spread through the departments of Landes and Basses Pyrénées, "where it is now abundant in waste places and along railroads."

The State Analyst of New York State having recently been requested by the Secretary of the State Board of Health to give his opinion with regard to the wholesomeness of cotton-seed oil and of lard and lard compounds into which this oil enters as a component part, has replied as follows: "I am clearly of the opinion that cotton-seed oil, whether used alone or commingled with other oils or fats, is a perfectly wholesome and nutritious food, and as easily digested and assimilated as any of the commonly employed fats. In support of this view the opinion of numberless writers upon the subject and of experts in chemistry and physiology might be adduced. Throughout the cotton-growing states it has been for a long time very largely used, and the medical faculty of the Arkansas University say that it is to be preferred to other fats in many respects, 'agreeing with the most delicate stomachs, whether used in baking or frying,' and that 'not one instance has ever been given of health being in any manner impaired by the use, however free, of cotton-seed oil in food.' They say that 'thousands of hands employed in the cotton-seed oil mills are in the habit of making their dinners on the crude oil by dipping their bread in it, and some of them actually drink it, and yet from this free use of it nothing has ever resulted but the best of health.'"

Professor B. D. Halsted in an article entitled "Observations on the Doubling of Flowers," published in the *Popular Science Monthly* for July, cites this instance of a doubling process. "In the *Petunia* the doubling of the flower is usually accompanied by a remarkable modification of the pistil—in short, a secondary flower is formed within the ovary. Botanists have long recognized an exceptional development of the floral axis which has been termed proliferation. In this there may be a prolongation of the axis beyond the blossom, and the development upon it of ordinary foliage. The European Larch furnishes a good illustration of this. Sometimes an ordinary leafy stem extends upward from the centre of the cone for nearly a foot. In rare cases leafy branches have grown out from the free or blossom end of pears, and buds and long branches have arisen from the centre of a rose. In the *Petunia* this proliferation, if we may call it such, assumes the form of a small and much contorted flower. Repeated examinations of normal flowers fail to show any unusual structure to the pistil. It is, therefore, associated with the doubling process in the *Petunia*. Instead of the end of the floral axis, which terminates at the base of the single centrally situated pistil, remaining as such, it develops into another flower, and this within the ovary of the primary blossom. Just why we should have this peculiar form of proliferation, or any, in fact, is not for us to decide. The ordinary forces which would construct a normal flower have been thrown into confusion, and retrograde metamorphoses and floral proliferation have resulted. In fact, it seems evident that out of the substance ordinarily producing a capsule of *Petunia*-seed has been formed in the same ovary an amalgamation of stamens, petals, and a rudimentary pistil. In short, the tendency to petaline display does not stop with the stamens, but invades the pistil, and transforms it as already described."

Country Roads.

THIS is the season when country roads make one of the staple subjects of complaint by the persons who have fled from the stifling heats of the city. These visitors, on recreation bent, find few inviting foot-paths when they wish to walk, and after returning from their first attempt to drive they usually write a letter to some newspaper complaining that the roads are stony or shadeless or dusty or muddy. It would seem that rural neighborhoods which lack the spirit or enterprise to keep good roads for their own comfort and profit would care little for the displeasure of transient visitors, but really the money brought into many country communities by summer visitors forms a considerable item in the sum total of their earnings for the year. Special attractions in the way of beautiful scenery or health-giving springs or pleasant lakes make a capital which often yields a remunerative income, and if all the attractions of perfect roads were realized it might be found that the money used in securing them would prove a most profitable investment by serving as an additional inducement to turn the tide of summer travel in their direction.

It is easy enough, however, to exhort persons to improve their highways, but it should always be remembered that special training and experience are required for the construction of a satisfactory road. Certain it is that a group of farmers who gather once a year to repair the roads can accomplish very little that is effective in this direction, and even when repairs have been made properly, and the road is left for an entire season to take care of itself, it will be as bad as ever when the annual mending-time comes round. Every year it is becoming more generally understood, as we are glad to know, that the roads must be made well in the beginning if they are to be kept well thereafter, and that slight repairs made during the year as they are needed are altogether preferable to the practice of repairing once for all. When roads are once well drained and well constructed the money which is annually expended upon them under the old system, with no satisfactory result, would amply suffice to keep them in excellent condition if it was entrusted to some competent engineer in charge of

the entire district. Many of the states have already adopted this township plan, under which all the road repairs are entrusted to a selected officer, and this is a marked improvement upon the old district plan, where the farmers worked out their tax. The necessity, too, of adequate training in this matter is so far recognized that a course of study in road-making forms a part of the curriculum of several of our agricultural colleges and some other universities. The invention of road-machines has also proved of great advantage in this respect, and although the material used is too often the scrapings of mud and soil from the gutters instead of gravel or pounded stone, nevertheless the roads repaired by machinery are usually much superior to those worked on the old system. Some of the states, too, have passed enactments by which the repairs of the main thoroughfares are provided for by a general tax, while only the cross-roads and by-roads are left to be cared for by the communities through which they pass, and the result of it all is that the roads in the eastern part at least of the United States are materially better in every respect than they have been in former years.

But even a good road—that is, a road which furnishes a smooth wheelway—may be an unattractive one, and it is worth while once more to call attention to the treatment of the road borders. Rural improvement societies, which have planted road-sides with shade trees, have done much in various parts of the country to mitigate the heat and dust which make driving unpleasant. Of course, it is not always advisable to plant a formal line of trees along winding roads and through a hilly country, but, as a rule, it will be found that trees however planted are better than none. We know of few instances, however, where systematic efforts have been made to preserve the growth of shrubs and wild flowers which spring up of their own accord. We have in a former number called attention to the work of the gardener of a great estate not far from this city who has thoughtfully planted the seeds of wild flowers along the bordering shrubs, which have been allowed to remain and fringe the road-side. Where one can see Blood-root, Bluets and Lupin with Cone Flowers, Painted Cup and Golden Rod and an increasing number of Ferns and Mosses embroidering the ledges of road-side thickets the way can never be uninteresting from early spring till late autumn, and even in winter, where the berries of the Black Alder and the hews of Wild Roses are left to glimmer among the soft tints of the leafless twigs of the shrubbery, the eye finds something to delight in.

Too often, however, all efforts at improving the wayside are made with the grubbing hoe and brush hook. The tidy farmer does well to cut down the brush along his fences, which otherwise would keep constantly encroaching upon his land, but this practice is not a virtue when it is extended to the fences which border the highway. It is true that in smooth and level countries where the wheelway is bordered by a greensward which is connected naturally and under open fences with the grass of the meadows and pastures, there is propriety in keeping down all other growth; but in stony and hilly regions where the bushes are cut away and nothing is left but raw ground and stumps the effect is unsightly. No formal planting can be more beautiful than the spontaneous growth of Nature's furnishing where the roads are lined with thickets of Black Haw and Cockspur Thorn, Sumac and Hazel Nut, with the Wild Grape clambering over the stone walls and festoons of Bitter Sweet swinging from the trees overhead, and Clematis and Ground Nut and Moonseed rioting over the shrubbery. No park-planting can excel such masses of foliage, and from the time when the June-berry and Dogwood and Wild Plum blossom in the spring, with Viburnum and Elder, Honeysuckles and Roses following in close succession, until the yellow Witch Hazel blossoms brighten up the border in late autumn, there is no lack of flowering shrubs. All that is needed to produce the most beautiful effects in this line is to allow these wild places to clothe themselves, to restrain the too rampant growth of the

stronger plants when they become too aggressive, and add an occasional touch, perhaps by setting some low-growing shrubs like Red Root and Sweet Fern on the edges of shrub belt, or planting some wild flowers in suitable openings.

Farmers often complain of the rates charged by transportation companies, but it would be easy to demonstrate that the carriage of farm products by rail and steamer, all combined, costs much less than the hauling of these products over country roads from the farm to the nearest railway station. This is not the place to enforce the argument for good roads by showing how much more rapidly and cheaply this hauling could be done if the roads were all good and in good condition. But, certainly, it is worth while to invite the attention of country landholders to the value of attractive roads. The first impression which a visitor receives of any region comes through its roads, and as he leaves, his last experience is on the road over which he is driven to the station. Every day, when he is not shut within doors, he makes use of roads and paths, and, although he may not realize the fact, a large portion of his pleasure or discomfort is due to their influence. Good roads pay by reducing bills for repairs of wagons and carriages, by saving time, by economizing horse power and in many another direction. The absolute money value of attractive roads to any country community is just as real and positive. They give an added value to every acre of land in the districts which they traverse.

THE people of California seem inclined to resent the statement of Major Powell that "the forests of the upper regions are not advantageous to the people of the valleys who depend on the streams for the fertilization of their farms." *The Century Magazine* for August publishes a letter from Mr. Abbot Kinney, who states from personal observation that in many cases the clearing away of the mountain forests has caused torrents in California which make the bottom-lands unsafe and he corroborates his experience by a number of references to leading authorities to show that the Major's theory is at variance with all the known facts of the case. A strong article, too, lately appeared in the *Alta California*, setting forth the dangers which threaten the forests of the western portion of the continent and expressing the views of all who are familiar with the forest-problems of that region. We quote a portion of this article which refers to forest-fires:

"Forest-arson is already in progress in California. The smoke from burning forests is beginning to soften the sunshine. It hangs over the waters of the bay and gives to all landscapes in every direction the soft and fine effects peculiar to the Indian summer in the east. These effects are purchased at too great cost, however. Thousands of acres of the noblest timber in the world will be sacrificed by fire between now and the first rains next fall. As usual, these forest-fires begin with the driving of sheep and goats into the mountains. In the coniferous forests there is not much pasture for these animals. The ground is covered by a carpet of the fallen needles and resinous cones. Under the Pines the Azalea grows. The sheep browse it, but it poisons them. Fire kills the timber, and when the carpet of cones and needles is destroyed some pasture will grow for a time. Fire also removes the Azalea. Is it at all remarkable, therefore, that fire is left in the track of the shepherd and his sheep? California mountaineers, who have practical knowledge on the subject, express their surprise at the views of Major Powell, of the United States Geological Survey, upon this subject, published recently in *The Century*. He strongly urges the good effect upon the forests of running sheep in the Sierras, and announces it as a prime method for preserving timber! A summer in the Sierras would work a change in his opinions."

The story of the wasting of the forests of the Sierra Nevada cannot be repeated too often; nor is it easy to overestimate the injury which Major Powell's utterances about forests in general are likely to work, coming as they do from the highest scientific officer of the Government. Positive opinions from such a source are apt to receive attention, especially when they appeal to selfish interests; and

Major Powell's recent remarks about our forests must bring great comfort to all the army of men who live illegally in one way or another on the forests of the public domain. As long as the officer, whose duty it is to furnish scientific information to the Government, declares that the forests of the western mountains are an injury to the country, timber thieves will continue to cut and shepherds will continue to burn these forests with new energy and with diminished dread of punishment.

White Park, Concord, New Hampshire.

THE capital of New Hampshire is a pleasant city of some 15,000 inhabitants. Its main street lies near the bank of the River Merrimac, and its residence streets stretch along the slopes of hills which rise irregularly west of the stream. Beyond the older streets, but surrounded by modern ways, is a small tract of land which is in part so precipitous and in part so swampy that all the new roads have avoided it. On this rough land is a fine growth of large trees of many sorts, and, although it lies only half a mile from the centre of the town, many of the most interesting New England wild flowers bloom in the shelter of its woods and hollows.

This tract of about twenty-five acres has been presented to the city of Concord, and is called White Park for the donor. A commission of well known citizens has been placed in charge of the work of fitting the ground for the use and enjoyment of the people, and they have wisely begun their labors by devising and adopting the general plan which is reproduced on page 395.

The Commission intends to make the park a place of quiet resort for people who cannot take the time or who have not the strength to go often to find refreshment in the open country. No carriages are to be admitted, not only because the acreage is small and the slopes steep, but also because it seems unfair to injure the park for the use of children and pedestrians while innumerable pleasant country-drives are close at hand. No elaborate gardening will be admitted, not only because it is costly, but also because it would be incongruous. Every city of the new West may have its carpeted "park" if it so wishes, but Concord proposes to seize her opportunity to provide for her citizens and their posterity something very much more valuable. She will set aside and preserve, for the enjoyment of all orderly townspeople, a typical, strikingly beautiful and very easily accessible bit of New England landscape. Would that every American city and town might thus save for its citizens some characteristic portion of its neighboring country! We should then possess public places which would exhibit something more refreshing than a monotony of clipped grass and scattered flower-beds.

The plan adopted by the Commission provides for the enhancement of the natural beauty of the park by spreading water in the lowland where nature made a marsh, by making grassy glades in two or three hollow parts where nature grew Alders and Birches, by planting a thicket of Mountain Laurel here and opening a vista to the Merrimac there; and then the plan leads paths in such directions and by such routes as will best display the beauty of the place while injuring it least. In the opinion of the Concord Commission, a path, far from being a chief beauty of a park, is only an instrument by means of which it is possible for large numbers of people to pass through the midst of beautiful landscape without seriously injuring it.

The variety of limited scenery which White Park will present when it is finished is great. Just within the main gate (at the end of the plan on the left) will be a level of green sward, bounded on three sides by rising banks, from which hang thick woods of deciduous trees. At one end the banks draw close together, and here is a deeply shaded dell, from the head of which a path climbs by steps to the street. Two other paths lead up from the green, by little hollows in the skirting bank, to a plateau where Pitch Pines stand in open order, and the ground is carpeted with their needles. A steep-sided, curved and densely wooded ridge in turn bounds this plateau, and beyond it, and nestled in the curve at its base, is a tiny pond, fed by strong springs, and overhung by tall White Pines. Its waters overflow, by way of a steep and stony channel, into a much larger pond, with shores but little raised above the water, which occupies the southern third of a long level, through which a slow brook meanders. The shore of this pond, and all the flat land near the brook, is scatteringly wooded with large deciduous trees. Paths reach little beaches on the shore at several points. Beyond the head of the pond a path leads to a "shelter" on a knoll in the midst of deep

woods, and thence by a sharp ascent to a high point on the very edge of the park, whence a pretty view will be had of the pond at one's feet and the Merrimac Valley beyond, with the state-house dome in the middle distance and near the middle of the picture. All things considered, Concord is in a fair way to possess one of the most charming small parks in America.

Why are gifts like this of Mrs. White to Concord not more common? Can any more valuable present to posterity be imagined? Perhaps they may be commoner when it comes to be known that there are now several park commissioners in this country who do *not* consider it their first duty to destroy the beauty which nature provides. Real landscape art is nothing if it is not broad, simple and conservative of natural beauty. It is elaborate and gardenesque only in special circumstances. Its old name of "landscape-gardening" must be discarded at once, if the definition in the new Century Dictionary is correct. Landscape art does not consist in arranging trees, shrubs, borders, lawns, ponds, bridges, fountains, paths or any other things "so as to produce a picturesque effect." It is rather the fitting of landscape to human use and enjoyment in such manner as may be most appropriate and most beautiful in any given spot or region. When this is generally understood by the public and practiced by the profession, parks and country-seats will be so designed as to be not only well arranged and beautiful, but beautiful in some distinctive and characteristic way, as is White Park at Concord.

The Alleghanies of Virginia in June.—II.

THE long, low colonial house at Eggleston's Springs, where we spent the night after leaving Salt Pond Mountain, stands in the centre of a wide, shady meadow, on the edge of the swift, muddy New River, and a few hundred yards below it are the fine limestone cliffs that rise up perpendicularly out of the water, several hundred feet high. The climb over a rough, stony trail to the top of this cliff is well repaid by the view of the curving stream and its beautiful, wooded banks.

On the highest ledge of the great buttresses grows the rare *Pachystima Canbyi*, a low evergreen shrub, only a few inches high, with narrow, serrulate leaves and curious yellowish roots. There is very little of it on the ledges; most of the plants, perhaps fortunately for their future, are quite inaccessible. It is in very select society, too, up there on its rock. *Berberis Canadensis* is close by on the edge of the precipice, so is *Rhus Canadensis*; and on the shady side of the cliffs, the Walking Leaf (*Campnosorus rhizophyllus*) "walks" over the mossy rocks, and quite a little company of Spleenworts (*Asplenium Rutamuraria*, *A. parvulum* and *A. Trichomanes*), grow close together under an overhanging boulder. Two pretty little white-flowered plants, *Arabis lyrata* and *Draba ramossissima*, grow on the cliffs, and *Clematis Viorna*, the Leather Flower, was in both flower and fruit. The long vines were covered with the dark reddish purple bells and the round, fluffy balls of the plumose-tailed fruit, and they climb over the bushes and hot rocks, where all down the face of one of the cliffs, in the blazing sun, the dainty, frail-looking little *Arenaria Michauxii* blooms undisturbed, and the pale, stiff *Pellaea atropurpurea*, the Cliff-brake, grows out of the many cracks. *Asclepias variegata* was just beginning to open its compact umbels of white along the path, bordered by dense clumps of *Rosa humilis* and little straggling patches of *Pentstemon pubescens*, where the air was heavy with the fragrance of innumerable wild Grape vines.

Our next mountain trip was from Buchanan, on the beautiful James River, to the Peaks of Otter, in the Blue Ridge, Bedford County, and beyond the assurance that there was a hotel near the Peaks, we could get no information from the natives at the station. It had rained heavily while we were in the train coming from Natural Bridge, the dust was laid, and from the start the scenery was finer, the forests older and in better condition, and last, but not least, the roads smooth and level in comparison with those on Salt Pond Mountain.

The picturesque Scrub Pine (*Pinus inops*), growing close to the road and scattered over the hills, made a delicious fragrance through the moist woods. The pretty Chinquapin (*Castanea pumila*) was in full bloom, and at a turn in the road, on the edge of the dense jungle, was a great clump of it against a background of the large, shiny leaves of the Black Jack Oak (*Quercus nigra*) and tall, overhanging branches of the Sorrel-Tree (*Oxydendrum arboreum*). The latter is almost a small tree in some of the thickets, its long finger-like racemes then covered with little round buds just ready to burst into bloom. The most striking plant on the first ascent is the Goats-beard (*Spiraea Aruncus*), with tall, compound panicles of pure white, feathery flowers. Big bunches of *Tephrosia Virginiana* fill the spaces between the bushes with pretty pink and yellow spikes, and the Fire Pink (*Silene Virginica*) makes a splendid show, for

anything more brilliant than its bright crimson stars would be hard to imagine. Two golden-yellow flowers, an Evening Primrose (*Oenothera glauca*) and *Coreopsis verticillata*, were abundant on the road embankment, where the little dark red-flowered *Galium latifolium*, the graceful pink clusters of *Asclepias quadrifolia* and the stiff, white-flowered *Euphorbia corollata* grow side by side.

A little further up on this same embankment we found the wonderfully pretty little relative of Shortia, *Galax aphylla*. The glossy, heart-shaped leaves are a bright light green, closely covering the ground, and row after row of the tall, stiff spikes stand up all through the underbrush. It had been just ready to bloom ten days earlier on Salt Pond Mountain, but here it was at its height, for the tall stems were covered to their tips with the beautiful little white flowers. When we reached the top of the first hill we saw for the first time *Kalmia latifolia* in all its glory of bright pink buds and great round bunches of white flowers. We drove up through tall hedges of it, the straggly, Japanese-looking shrubs filling the swamp with patches of white against the light green young woods beyond; and all around the edges of the marsh we found *Oakesia puberula*, *Anemone trifolia* and *Pogonia verticillata*, all three already in fruit, and on the top of the hill *Parthenium integrifolium* and *Anianthemum muscatoxicum*. This latter plant, belonging to the Lily family, has tall spikes of flowers, and was so abundant that the whole swamp was a waving mass of white, while over everything twined and twisted the large, pointed leaved vines of the Wild Jam-root (*Dioscorea villosa*).

The road-sides are bordered by splendid round-topped Chestnuts, *Magnolia acuminata*, in plenty, and here and there a few Hemlocks along the water-courses. Some of the Oaks are magnificent, and by far the finest of the larger trees on the mountain.

The road led under the brow of a long ridge for a couple of miles, and at every turn the view grew grander and more varied. It was eight o'clock before we reached the hollow between the two peaks, where we supposed the hotel was. Our colored drivers, who, notwithstanding their protests to the contrary, knew absolutely nothing about road or mountain, were entirely at sea till an obliging farmer informed us that the house was on the top of the mountain, and had been there for the last twenty-five years, and that we could only drive a few hundred yards further, after which we should have to walk up 700 yards or so to the summit. The road was so steep that we all left the wagons and walked in the gathering dusk to the small log hut, where the horses were left, then in the pitch darkness tried to keep in the narrow stony trail, and at ten o'clock, a tired, bruised party, reached the "hotel," a small log cabin and a tiny kitchen, perched between two huge boulders on the windy summit. Mr. Rosser, the proprietor, an old negro servant, and his daughter, the cook, some dogs and chickens, and a flock of wild white Angora goats, are the only inhabitants of this lonely eyrie, from which in all directions we could see, shining out of the darkness far down in the valleys below, the lights of Roanoke, Lynchburg, Liberty and those of the many smaller settlements grouped around them.

The accommodations were not luxurious, but we were passably comfortable, and when called at five o'clock were ready for a day's hard climbing. The sunrise from behind the misty Blue Ridge was a sober one that morning, but the view was magnificent. Range after range of the forest-clad mountains of West Virginia lay to the west, and at our feet a few wooded valleys and foot-hills, and then the wide fertile plain that stretches south through Virginia and North Carolina toward the Atlantic.

In the cracks of the rocks and among the loose stones all about us, but only on the very top of the peak, grew luxuriantly *Dicentra eximia*, the long, drooping racemes of curious pale pink flowers closely resembling those of the cultivated Bleeding Heart. The two ornamental shrubs of the summit, and the only ones, were *Rhododendron Catawbiense*, its big, deep pink bells bright and fresh in the morning light, and the American Mountain Ash (*Prunus Americana*), a very striking little tree, with wide, flat cymes of creamy white flowers. *Diervilla trifida* grows quite bushy not far from the top, and a projecting group of boulders, "The Needles," is carpeted with the small *Paronychia argyrocoma* in dense silvery looking mats. The Wild Columbine (*Aquilegia Canadensis*) was hanging out its bright red and yellow bells up there twice the size that they attain in the valleys. We found *Lilium Grayi* all through the woods, but we were too early for the flowers, as we were too late for those of *Clematis verticillaris* that grew further down.

Asarum arifolium was growing in a damp spot near the

small spring below the summit, and close by on the rocks were pretty little clumps of the delicate bluish *Houstonia purpurea*, var. *longifolia*, and along the road below were great masses of the showy Purple-Flowering Raspberry (*Rubus odoratus*).

The twelve-mile drive on the return to Buchanan was, if possible, more beautiful than the ascent, and when the valley was reached we were unanimously in favor of returning at some later season of the year, for the promise of autumn flowers was enchanting. It would be hard to find anywhere a spring trip offering more beautiful and varied scenery, nor a more easily accessible one. Along the valleys the railroad companies are putting up everywhere charming little "Queen Anne" inns, in which the accommodations and fare leave little to be desired, though off the beaten track, roughing it must be accepted with good grace. The trains are marvels of unpunctuality, and time down there is no consideration whatsoever; but these defects were made up for by the politeness and attention we received from the trainmen and their evident desire to make every one as comfortable as possible.

New York.

Anna M. Vail.

Earliness With Unripe Seed.

THERE seems to be a fair amount of evidence to prove that seeds from immature fruit will give a product requiring less than the usual time to ripen, and that the earliness thus gained can be increased by continuing the selection. The strain of Tomatoes from green seed, mentioned by Dr. Sturtevant in his timely notice of the subject in a recent number of GARDEN AND FOREST (page 355) is still grown in the garden of the Indiana Experiment Station, and with increasing interest. The present season is the fifth generation. A report on the result of this study will eventually be published. Some information gathered from this and other attempts to investigate the subject of the relation of unripe seeds to the development of divergent characters in the product makes clear some points which it will be well to bear in mind in any attempt to apply such a method to the production of early varieties.

It is not the slightly unripe seeds that give a noticeable increase in earliness, but very unripe seeds, gathered from fruit scarcely of full size and still very green. Such seeds do not weigh more than two-thirds as much as those fully ripe. They germinate readily, but the plantlets lack constitutional vigor and are more easily affected by retarding or harmful influences. If they can be brought through the early period of growth and become well established and the foliage or fruit is not attacked by rots or blights, the grower will usually be rewarded by an earlier and more abundant crop of slightly smaller and less firm fruit. These characters will be more strongly emphasized in subsequent years by continuous seed propagation.

In the observations so far made, it has been found that the plant as well as the fruit tends to early ripeness, and so the period of fruitfulness—that is, the time between the first and the last ripe fruit—is much shortened.

With the increase in the amount of fruit there is also a corresponding decrease in the size of the vegetative parts of the plant—that is, the stems and foliage. A Tomato plant grown from green seed in the fourth generation was found to bear three and a half times as much fruit as tops—that is, stems and leaves together—while a similar plant from ripe seed had but one and an eighth times as much fruit as tops.

It therefore follows logically that while earliness may be considered as a usual condition in all crops from unripe seed, an increase in the amount of the crop only occurs when the true fruit is the part harvested, as in Tomatoes and Peas, and a decrease in the amount of the crop occurs when any part besides the fruit is harvested, as in Turnips and Potatoes.

Whether any method can be found to counteract the enfeebling of the plant and yet preserve earliness remains to be seen.

La Fayette, Ind.

J. C. Arthur.

Plant Notes.

Tecoma grandiflora.

THE figure of *Tecoma grandiflora* on page 393 is from a photograph of a plant grown in a pot in a greenhouse and exhibited at the last (June) Rose Show of the Massachusetts Horticultural Society by Mr. James H. Comley, gardener to Mrs. F. B. Hayes, of Lexington, Massachusetts. Mr. Comley states that he received the original plant, without a name, from Mr. John Cadness, of Flushing, New York, some six or seven years ago. For the

last five years the plant has been growing in the open air at Lexington without any protection except that afforded by a stone wall, against which it is planted, and by some surrounding shrubbery, and it seems to be almost as hardy as our native Trumpet Creeper (*T. radicans*), which is its near ally. It blooms freely every year, beginning early in August, and continuing to produce flowers for six or eight weeks, or until checked by frosts. Even when the whole plant is cut back to near the ground a profusion of flowers is produced on the strong, new shoots the first year.

Our figure represents a plant grown from a hard, or ripe, wood cutting, taken from the open-air plant in the autumn of 1889, and therefore about eight months old when exhibited. It is undoubtedly *T. grandiflora*, a Chinese species, which has also been introduced from Japan, where it appears to be known only in cultivation. It was introduced into England in the early part of this century, and in 1811 a figure was given in the *Botanical Magazine* (t. 1398) under the name of *Bignonia grandiflora*.

T. grandiflora is a climbing plant, like *T. radicans*, although it does not appear to grow so rampantly or to produce climbing rootlets on the stems so freely as the latter. The seven to thirteen ovate, pointed leaflets composing each leaf are of a lighter green and more coarsely toothed than those of *T. radicans*, which also differ in being more or less pubescent beneath. Instead of being produced in short terminal bunches at the ends of the branches, the flowers of *T. grandiflora* form large spreading panicles. The young calyx-covered flower-buds gradually taper to a point, and are noticeably five-angled, instead of being rounded and terminating abruptly in a small point, as in our common species. The magnificent bell-shaped flowers are from two to three inches deep, while the wide spreading mouths average three inches across. They are of a bright, light orange within the tube, orange-red with darker streaks on the outer spreading portion, while on the outside they are a soft salmon-yellow. Altogether the colors are much more pure and rich than those of the native flowers.

It does not seem to have been generally known, in this country at least, that this *Tecoma* would flower at so early an age, and therefore it has been suggested that the plant illustrated represents a specially precocious strain or variety. Indeed, it was exhibited under the provisional name of *T. præcox superba*. It is not improbable, however, that any plant of the species when treated in the same way would bloom as early. A plant received from Veitch last year is now flowering in the Arnold Arboretum. Mr. Parsons, of Flushing, who prefers to propagate it by grafting on *T. radicans*, has a plant in a three-inch pot which was grafted last winter and has just now finished blooming.

As already shown, this beautiful *Tecoma* is well adapted for forcing, and it may be propagated by hard or soft wood cuttings or from pieces of the root. For pot or out-door culture the plant may be very easily trained in a dwarf, bushy form.

Like many other exotics this was grown as a greenhouse plant when first introduced into cultivation in Europe, and it may be said to flower most freely when forced by artificial heat.

The plant shown in the figure is now producing flower-buds on new shoots which have been thrown out.

The Virginia Creeper.—This luxuriant climber is the best substitute we have for the English Ivy in cold climates where *Ampelopsis tricuspidata* is not hardy. But those who plant this vine with the expectation that it will cling to brick or stone walls are likely to be disappointed unless they select the variety with much care. The fact that an individual vine of this plant clings tenaciously to the trunk of a tree is no sure indication that it will attach itself to a wall. The tendrils on different plants vary much in their structure. On some they are much like those of the Grape, coiling about objects with which they come in contact, but little branched and producing no sponge-like disks at their extremities. Such vines will climb up the trunks of trees having rough bark, but they are

Fig. 50.—*Tecoma grandiflora*.—See page 302.

unable to attach themselves to walls. In another variety the tendrils branch into several divisions, each of which is terminated by a flat, sponge-like disk that unites itself with considerable tenacity to hard and comparatively smooth surfaces.

On the grounds of the University of Wisconsin the Virginia Creeper is much at home, coming up spontaneously about the

whole campus. Attempts have been made to train it over the walls of the stone buildings, but these have been successful only in a few instances, where the variety was the one bearing the branched and disk-bearing tendrils above described. One variety seems especially well suited to the purpose, the foliage being very dense, the tendrils uniting themselves firmly and

the younger leaves having an attractive purplish tint. The tendrils on different seedling plants exhibit all forms of variation between the grape-like ones and the much-branched, disk-bearing ones.

Nurserymen would do well to propagate varieties with especial reference to their climbing properties, the density and shade of their foliage, and the quality of retaining their leaves after they have assumed their brilliant autumnal hue.

University of Wisconsin, Madison.

E. S. Goff.

Iris Gatesii.—This new Iris, for which we are indebted to the energy and enterprise of Herr Max Leichtlin, has flowered lately in a few collections in Europe. It is larger and more attractive even than *I. Susiana*, hitherto considered the king of the genus. Max Leichtlin is reported to have said of *I. Gatesii* that it has "the most aristocratic appearance of any flower that has ever passed through his hands." Professor Michael Foster, the high priest of the Iris cult, described it last year in the following words: "Imagine a flower often very much larger than *I. Susiana*, of a delicate light gray hue, resulting from minute dots and delicate veins of a rich purple on a creamy white ground, or at times of a pure light sky blue, marked with deeper veins, and at the same time of peculiar grace and form." The plant is a native of Armenia, and requires the same treatment as *I. Susiana*, to which it is closely affined. It was named after the Rev. T. F. Gates, of the American Mission at Mardin. A figure of it from a plant flowered by Max Leichtlin has lately been published in the *Gardeners' Chronicle*.

I learn from Mr. De Graaf, of Leiden, that to succeed with *I. Susiana* and its allies the treatment must be more liberal than is usually afforded. Mr. De Graaf grows these plants by the thousand, and treats them exactly as he treats Tulips and Crocuses—*i. e.*, lifts them and stores them dry for the winter, and replants again in early spring in rich soil in open beds. Those who have tried the dry frame treatment for this section of Irises should try also that recommended, and, moreover, proved most successful, by Mr. De Graaf.

Notes on American Plants.

ONE of our most showy biennials which blooms the last of July is the *Sabbatia chloroides*, a species of the American Centaury. The whole plant is somewhat slender, seldom over eighteen inches high, with a few not large, oblong-lanceolate leaves. The flowers are single at the extremities of a few slender peduncles about two inches wide and rose colored. They open in the middle of the day and close at night. The plant is often bent down at time of flowering, owing to its slender stems. It inhabits the "borders of brackish ponds" from New England southward, and it seems to prefer a moist, sandy soil on the margin of some pond or stream. When once established in a suitable locality it would no doubt continue from year to year and it is surely one of our most desirable natives.

Baptisia tinctoria (Wild Indigo), a herbaceous perennial, two to three feet high, with many spreading leafy branches bearing numerous light yellow flowers half an inch long near the ends, is a useful plant in many places, and it flowers about the middle of July. The three oval leaflets are about the size of those of the White Clover and much resemble them. It thrives on the poorest sandy plain-land, along the borders of woods or in open fields. Its foliage alone is worth the trouble of growing it, and when once established it seems to require little or no attention.

Calochortus macrocarpus, one of the later flowering species of the Butterfly Tulips, is a plant in greater demand among European dealers than most of this genus. Its large, showy, lightish purple flowers, more than two inches wide, are hardly excelled by any other species. But in our light, sandy soil and climate it is almost a total failure. The plants in early spring showed much vigor and sent up strong flowering stems, but before the buds were half grown the leaves died and only a few flowers ever opened. Perhaps a heavier soil would suit it better.

Cooperia is a genus belonging to the Amaryllis family, of which we have received three species from southern Texas. They much resemble some of the species of *Zephyranthes*, and might easily be taken for them. The plants come from a spherical, medium-sized bulb, have long and narrow grass-like leaves, and naked scapes about a foot high which bear a single white or pale rose flower. *Cooperia pedunculata* is the largest and strongest species and the first to flower by more than a

week. Its more numerous leaves are wider than in either of the others and the plant seems the most desirable of the three. *C. Drummondii* and another called *C. Oberwetteri* are smaller, with narrower and more slender leaves and smaller flowers, coming into bloom about the same time, ten or fifteen days later than the first. Like most bulbous plants from the south they should be wintered in dry sand in a cellar.

Zephyranthes Texana, from southern Texas, has a reddish yellow flower with darker stripes, nearly an inch wide. The outside is still darker. Its foliage is very scant and at time of flowering there is little but the almost naked scape and flower to be seen above ground. Its height is hardly eight inches. The flowers last about two days.

Nemastylis tenuis is a showy little species from Mexico. Here in our northern climate it attains a height of only five inches, but it bears a bright yellow flower, with a slightly darker centre, an inch wide. The leaf is small and not conspicuous, and about all there is visible is the flower and its slender stem. The bulbs are small, half an inch or thereabouts in diameter, and covered with thick coating, to protect them from prolonged drought.

One of our most charming little natives at this season is *Talinum teretifolium*, a low, leafy-stemmed plant, with a peduncle about five inches long bearing an ample cyme of pink or rose-purple flowers over half an inch wide. It acts like an annual, but of this I am not sure. At all events, it flowers from seed the first year, and plants that bloomed last season did not come up this; but the open winter might have killed them. It seems to do best in shade.

The Marsh St. John's Wort (*Elodes Virginica*), with its pink or flesh colored flowers and numerous oblong-ovate clasping leaves, makes a pretty garden plant, now in flower. Its height is about fifteen inches, branching near the top. Its flowers are in small clusters and are about half an inch broad. It is a useful plant for the artificial bog, or it thrives well in any fine loamy soil in the shade or sun.

Asclepias verticillata (Whorled Milkweed) comes into flower the latter part of July. Its height is about fifteen inches, and its very numerous narrow leaves, which are in whorls at regular intervals along the stem, are about two inches long, and about six in a whorl. The flowers are nearly white, in several small umbels at and near the summit of the simple stem. It is an attractive, hardy perennial, easy to grow, and thrives in shade or sun.

The Wild Senna (*Cassia Marilandica*), which flowers here about August 1st, is one of our most valuable native perennials—a member of the Pulse family. Strong roots send up several stout, but simple, leafy stems, three or four feet high and bearing near and at the summit numerous lateral racemes of yellow flowers. Its foliage is fine from the time it matures until frost, and its flowers are also very pretty. It is not partial as to soil, but it will do well in any ordinary garden soil, and may be planted in either spring or autumn.

Tigridia Pringlei (see vol. i., p. 389, Fig. 61) prefers a heavy soil—a clay loam—to that of light sand with little or no clay; and this seems to be the case with most *Tigridias* we have tried. It has greatly improved in the three seasons of cultivation, the old bulbs being more than double their size when first gathered, and they bear larger and richer colored flowers. In one respect it is quite unlike most of the species common in cultivation, and that is, it is not much inclined to increase by the division of its bulbs. This season, in the light soil where we set it, the plants are hardly two-thirds as tall and the flowers are fewer and smaller.

Rational Pruning of the Raspberry.

THE Raspberry-plant is a sort of compromise between a perennial herb and a shrub. Its stems are woody, but instead of living on from year to year, and bearing an indefinite number of crops like the Currant, it lives but about a year and a half, and, like a multitude of other plants, perishes after maturing its seed, while its roots live on indefinitely. Like many of the herbs, the stems make a very rapid growth until they have attained their normal stature, when, in common with their branches, they terminate in a cluster of flowers, followed in due time by the fruit. Such would be the case, at all events, but for the fact that winter usually intervenes before the normal growth is completed, and destroys the terminal bud, leaving the future growth to be made by the axillary buds that have not yet started into vegetation.

This explanation should give us a clue to a rational method of pruning the Raspberry (and Blackberry as well), which has long been a sort of mystery to many growers of these delicious fruits. Why prune them at all? There are two

reasons, one of which has already been suggested. Winter comes on, at least in our climate, before the growth is completed, and usually destroys more or less of the immature and succulent terminal parts. It is better to remove this destroyed portion, because if left it continues to absorb and transmit by evaporation the sap brought up by the living part of the cane, thus robbing in a measure the fruit and foliage. This pruning

would naturally be done in the spring as soon as the buds begin to swell. Earlier than this it would be difficult to decide how much to remove; later, the dead portion would already have wrought a part of its mischief. The other reason for pruning is suggested chiefly, if not wholly, by the convenience of culture. The canes of the Black-Cap Raspberry (*Rubus occidentalis*) grow to such a

length as to greatly interfere with cultivating the plants and gathering the fruit unless they are dwarfed in some way by treatment. By permitting them to grow to their full length, and then cutting them back to a convenient stature, we should remove one-half or more of the fruit-buds, and thus materially reduce the crop. We must prune them in such a way that while we keep them down to a size that is convenient for working among them, we also preserve the flower-buds. To accomplish this we pinch the terminal shoot at the height of two to two and a half feet. This causes the buds in the axils of the leaves to develop into branches, and instead of a single cane six or eight feet in length we have half a dozen branches two feet or less long.

To the beginner it appears almost absurd to pinch a Raspberry-cane at the height of two feet. It seems as if the cane has but just commenced to grow, and that to pinch it at that height will prevent it growing taller. But it should be remembered that there are several nodes at the top of the stem that have not attained their full length, and which will continue to elongate for some days after the tip has been removed. A cane pinched at two feet will attain an ultimate height of three feet, which is sufficient.

It has often been recommended to pinch the branches when they have attained the length of a foot from the main cane. The wisdom of this is quite doubtful, at least in regions of severe winters. The effect of it is to cause axillary buds upon the branches to develop into shoots, and this will take place so late in the season that they have not time to make much growth, and, being immature, they are liable to kill back badly during winter. The result is that the buds that should have remained dormant until spring to furnish the flowers for the crop have been forced into growth in late summer, while the tender buds upon these immature shoots—all that are now left to furnish the crop—have either been killed outright or severely weakened by the winter. It is doubtless, in the majority of cases, better to let the branches from the main cane grow undisturbed until autumn and then cut them back as far as seems desirable at the spring pruning.

The canes of the Red Raspberry (*Rubus strigosus*) do not attain such great length as those of the Black-Cap type, and so do not, as a rule, need pinching in summer. When vigorous growing varieties like the Cuthbert are planted in rich soil the canes sometimes attain an inconvenient height. In such cases they may be pinched like those of the Black-Caps, but the pinching will tend to stimulate the growth of suckers, an evil which needs no encouragement, because it is apt to be excessive in rich soils even without the pinching. It would probably be wiser to substitute a weaker growing variety, or else to remove the plantation to poorer soil.

The reasons given for pruning the Black-Cap type of Raspberries will apply as well to the Blackberry.

E. S. Goff.

Disa grandiflora.

THE York nurseries have long been famed for the cultivation of this superb Orchid, which, when well grown, is very much superior to all other terrestrial species. It is, however, often a failure in English gardens, even when managed by growers of undoubted ability. The treatment which answers so admirably with Messrs. Backhouse, of York, appears simple and within the means of any one possessing a cold-house or frame. At a recent visit there I found over 1,000 spikes of the flowers of this *Disa* all in a house, or a portion of a house, some twenty yards long. Many of the spikes measured a yard in height, and five flowers on a spike were not infrequent. The house is a low span, running from north to south, with a central path and brick beds about four feet wide. The surface of the bed is about eighteen inches from the glass at the back, and is formed of sandy peat, with large pieces of soft sandstone scattered through it. The depth of the soil is about six inches, below which are clinkers and brick rubble. The best of peat is used, and the plants are always placed against a large piece of sandstone, an important point not to be overlooked. In this they soon establish themselves, sending out runners freely in all directions, so that if allowed to remain undisturbed for two or three years each plant becomes a many-headed tuft. The soil is kept moist, but not excessively so, injury resulting from too free watering even in the case of this plant, which in its South African haunts is often semi-aquatic. The house is shaded all day by a thin canvas blind, and the whole of the roof glass is drawn off both day and night in all favorable weather.

This is the whole secret so far as Messrs. Backhouse can reveal it. On the other hand, some cultivators grow this *Disa* well by planting it in a mixture of peat, sphagnum and brick

rubble or sand. But not even on Table Mountain is it possible to see a more glorious display of flowers than is produced annually in the famous York nurseries.

When we come to examine the plants we find considerable variety in the form and colors of the flowers far beyond anything described as occurring in nature. This variety in cultivated plants is accounted for by the fact that both in Messrs. Backhouse's hands and elsewhere in England seeds have been matured and large numbers of seedlings obtained from them. Sometimes it is possible to obtain strong flowering plants of this *Disa* in three years from seeds. According to Bolus, Trimmen, and others who have studied the habits of *D. grandiflora* at the Cape, wild plants are not known to mature seeds. Trimmen stated that he had never found any trace of insect agency in this plant, and Bolus, in his "Orchids of the Cape Peninsula" (1888), says, on this point, "I have never seen a matured seed vessel, nor been able to detect any insect employed in its fertilization. On its native mountains it has a wide range of altitude, grows vigorously in dense masses, or at least several together, being apparently propagated exclusively by the formation of new tubers, and isolated plants (such as might be expected if it seeded freely) are rarely to be seen. Considering the brilliant colors of the flowers these facts are remarkable, and seem to point to the extinction of the insect by which this species was originally fertilized." "Artificial fertilization and selection, although only comparatively recently applied to this species, have already produced remarkable results in the shape of variety. If this plant could be grown with the same ease and success everywhere as it is by Messrs. Backhouse we should probably in time get a race of varieties as diverse in character as Zonal Pelargoniums."

Kew.

W. W.

A Few Strong-growing Adiantums.—II.

A HANDSOME variety of *Adiantum trapeziforme* is known as Cultratum, and it bears some resemblance to the type, but has smaller pinnules. The young fronds, when developing, are brownish and sometimes tinted with pink, finally turning to dark green with shining black stipes, and frequently attaining a height of three feet or more. This peculiar shading of the young fronds is one characteristic which distinguishes this variety from *A. trapeziforme*, as the latter almost invariably comes up pale green in color. It may be said, however, that the tinting of the young foliage in Adiantums is not always a reliable characteristic to judge by, as differences in exposure as to light or shade may make some difference in the color of some varieties, though not in all.

A. digitatum is another fine species, and, like the preceding, is a native of Brazil and some other portions of South America. It throws up its light green fronds on slender footstalks from one and a half to two feet in height. The fronds are rather irregular in general outline, and are usually three times divided. *A. digitatum* grows best in a warm house temperature, and, as the fronds are rather brittle, it generally requires a few stakes to keep it in form. It is a very distinct species, having pinnules from half an inch to an inch in diameter, and when well grown makes a handsome specimen.

Still another fine Brazilian species is *A. intermedium*, also a stove species, and a notably good one, its massive-looking, dark green, bipinnate fronds, with somewhat woolly stipes, being both ornamental and useful, as they last well when cut and placed in water. While yet small, *A. intermedium* is a good species for window-ferneries, and, as the spores come up freely, it may be readily had for this purpose. This species has as synonyms *A. Brasiliense* and *A. triangulatum*.

A. Wilesianum is a very handsome species from Jamaica, and it is not very common, probably from the fact that it does not produce so many spores as some other species, and the propagation of it thus depends in a measure on division of the crowns. *A. Wilesianum* is somewhat similar in general appearance to *A. cardiochlena*, though abundantly distinct from the latter. It bears broad fronds that are two feet or more in height and pale green in color. The fronds have shining black stipes which stand up well without support and form an admirable contrast to the delicate coloring of the pinnæ. This species will also be found to grow best in a temperature of about sixty degrees.

A. tetraphyllum gracile is another effective species, the fronds averaging from one to one and a half feet. The young fronds of this species are specially attractive, being bright pink in color, which gradually fades as the frond attains its growth, when it becomes dark green. The fronds of this variety are easily injured by excessive dampness, and it is best therefore to keep the water off the foliage as much as possible, though an abundant supply at the root is necessary. This species,

like so many of the finest of the Maiden-hairs, is of South American origin, being found in Colombia.

A. Aneitense is a fine addition to the genus, made within a few years. It is evergreen, of free and rapid growth, and soon becomes a shapely specimen. Its fronds have some resemblance to those of *A. fulvum*, but are stiffer and harder, and more lasting when cut. This species seeds very freely and the spores germinate quickly, so that it is as easily multiplied as the ever popular *A. cuneatum*. *A. Aneitense* averages about eighteen inches to two feet in height and thrives in a temperature of fifty degrees.

A. curvatum should not be omitted in any good collection, though it has not an excellent reputation for free growth, being often considered difficult to manage. The fronds are large, tripinnate, and very bright green in color, with stipes more or less hairy, the pinnules being curved back to such a degree as to give them almost a sickle shape. This is a stove species and requires heavy shading to encourage its growth, and the soil I have found most satisfactory for it is nothing but rough, fibrous peat, broken into lumps that may be only limited in size by the pot to be used. With this soil and abundant drainage material in the bottom of the pot or pan I have always secured fine plants.

Perhaps it should be said that the *Adiantums* of more delicate habit have been omitted from these notes, not from any lack of appreciation, but simply because this arbitrary classification is convenient.

Holmesburg, Pa.

W. H. Taplin.

Cattleya Warneri is one of the best of summer-flowering varieties. Its relation to the Labiate section can easily be perceived in growth and habit. The flowers are large, most of them measuring seven inches in diameter, and the lip is from two to two and a half inches across. The sepals and petals are of a most beautiful rose color, the best varieties having a rich magenta-crimson lip, very finely fringed. We have a few plants with such a lip, but the greater portion of them vary much, both in color and form. In the many plants we have there are very few with a lip of the same shade, every variety being distinct. The durability of the flowers is surprising, some lasting five weeks in perfection. We have had a display of this most magnificent *Cattleya* for ten weeks, the last flower having just faded.

We grow it in glazed pans about five inches deep and made with holes dotted here and there in them. The glazing seems to help the plants in many respects; for instance, they need no washing, and therefore the roots never get damaged from this process, and they always keep sweet and clean. We fill them within an inch of the top with potsherds, and cover these with a layer of moss; then the plant is firmly potted in a compost of fibre and sphagnum moss and charcoal, taking care to have it well up above the top of the pan.

We never allow our plants to remain dry for any great length of time, as they make their growth in winter and an abundance of roots in summer. They are suspended from the roof, where they get all the light possible, and at all times, except when in flower, when they are put in a more shady place to preserve the flowers as long as possible.

These plants never fail to flower with this treatment, and most of the spikes carry three and four flowers.

Staatsburgh-on-Hudson.

F. Atkins.

Cytisus scoparius Andreanus.—This beautiful new variety of the common Broom received a first-class certificate of merit at a recent exhibition of the Royal Horticultural Society. I recently saw the plant in bloom at the nurseries of Messrs. Temple & Beard, at Cambridge, and it certainly deserves this honor. In habit the plant resembles the common Broom, to which Linnæus is said to have rendered homage on first seeing it in bloom. In the typical plant the blossoms are clear bright yellow, but in this variety the lower part of the flowers are of a rich crimson-brown, which gives it a very distinct appearance when in bloom. It is said to have been found some five years ago in Normandy, and it has proved perfectly hardy in English gardens, where the typical plant and a white-flowered variety are often cultivated for their beauty as garden shrubs. *Cytisus scoparius* has been found to be perfectly hardy in New Jersey, and this being so, we may reasonably hope that André's variety will eventually be added to the list of beautiful plants for New England gardens; and the list will never be too long to admit novelties of such merit as this one possesses.

Achillea serrata plena.—The old *Achillea ptarmica* has long been valued in gardens for its pretty clusters of double white flowers, and florists often cultivate it on account of the dura-

bility of the flowers when cut; but the introduction of the double *Achillea serrata* will almost certainly result in the discarding of *A. ptarmica*. This latter has smaller flowers, and fewer of them, and is of a sprawling habit. A shower of rain bespatters the flowers with mud and renders them useless. *Achillea serrata* grows fully four feet high, and fully three feet of the stem produces useful side branches, with terminal heads of pure white, very double flowers, fully twice the size of those on the older plant. The quantity produced on the stems renders them top-heavy, and a stake is necessary to keep them erect. We have been cutting for the past month from this plant, and shall continue to do so for a week or two more, so that it can be easily seen that the plants hold out well, even in dry weather such as we have recently experienced. It may not be generally known that these *Achilleas* are readily propagated from the underground shoots or stolons. After flowering in fall the plants may be lifted and placed in soil until January, when the stolons may be taken off, curled around in three-inch pots and covered with soil; they will commence to grow at once, making strong plants for the garden in April, and will flower abundantly during summer. When these double *Achilleas* get old it is always best to take them up and raise young stock. This treatment will always pay for the trouble involved.

South Lancaster, Mass.

E. O. Orpet.

Dianthus semperflorens Marguerite.—This interesting Carnation, first offered in seeds and plants this season, is a new strain of Remontants originated by M. Boncharlet Jenne, the well known French horticulturist. Seldom does a floral novelty so fully bear out the claims made for it, for this proves to be a valuable race, with remarkably good points. The plants are rapid, vigorous growers, with good foliage and good habit, of medium height, and may readily be had in bloom in between four and five months from seed. The flowers are of fair size (sometimes of thin texture), often well fringed and fragrant. The seeds are said to produce ninety per cent. of double flowers, but no single ones have appeared among my plants. My flowers are very double, scarlet and rose. It is said there are pure white and striped ones in the race. The plants have every appearance of being of a "perpetual," free-flowering character, though it is not, of course, possible to report on this without further experience. It is scarcely necessary to say that such a race of Carnations is a great gain, enabling every one to readily secure a supply of most valuable flowers for the summer decoration of the garden. The usual "florists' varieties" of Remontants seem to be of not much value for garden purposes, as commercial growers have naturally given their attention to those most serviceable for blooming under glass and producing long stems.

Elizabeth, N. J.

G.

The Forest.

The Sihlwald.—III.

BEGINNING in rights of usage rather undefined until the opening of the fourteenth century, the rights of property of the free City of Zurich in the Sihlwald extended in 1309 to complete ownership in the forest, and have since been disputed only at the time when, following upon the events of 1798, the free city changed its government to that of a municipality under the confederation. But the rights of the municipality of Zurich in the Sihlwald were definitely confirmed by the so-called Mediation Act of 1803, and the possession of the forest was assured to the city which had so long enjoyed it. Evidences of the care which the burghers bestowed upon it are found in the series of ordinances which, beginning in 1309 with a rule that no forester might cut wood in the Sihlwald—clear proof that a forest-police existed at that early date—continued in unbroken succession to that of 1417, under which the foundation of the present organization was laid, and finally, in 1697, reached the first technical working-plan. It is curious to note as an indication of the view of the nature of its interest in the forest held by the city, that the policy of adding to the public forest-property by purchase, recently inaugurated by the Legislature of the State of New York, was begun by the free City of Zurich nearly two centuries before the discovery of America. It is true, however, that the property has been diminished at times through sales and especially through grants of land for the extinction of servitudes; but the purchase of over four hundred acres during the last fifty years leaves no doubt of the tenacity with which Zurich holds to its forest-inheritance.

The administration of this historical bit of woodland is subject, in common with that of the forests of communes, public

institutions and corporations and private forests necessary for protection, to inspection by the forest-officers of the Canton and the Confederation. Its chief, Forstmeister Ulrich Meister, who holds his office directly from the city, is at the head of a staff which comprises, besides a first assistant with the rank of Oberförster and a variable number of young men who are completing, under his orders, their year of practical work, four trained foresters and a permanent force large enough to carry on the whole lumbering, manufacturing and administrative work of the Sihlwald. And herein lies the chief reason why such an amount of delicate work in the way of silvicultural operations is so cheaply and excellently done. Every wood-chopper in the forest is familiar with the methods of planting and thinning as well as the manner of felling required to ensure the best results, and work which is thought in France to demand the presence of a forest-inspector is here successfully executed by common laborers under the somewhat loose supervision of a forester of the lowest grade.

The financial management, on the other hand, whose avowed object, unlike that of the Forest Administration of the French Government, is to produce the greatest net return in money and not in material, is rigorously centralized and exact. Monthly balances and reports of stock, submitted to Herr Meister and the central office at Zurich and compiled into an annual document at the end of each year, make it easy for the Forstmeister to control the affairs of his forest. Economy as strict and watchful as that of any private enterprise prevails wherever it is consistent with the best interests of the forest; but when its welfare and completeness or the attainment of a scientific silvicultural result is at stake, a wise and open-handed liberality appears. Under this management the Sihlwald gave last year a net return of something over \$8 per acre, or a total contribution to the treasury of the city of about \$20,000. This sum, large as it is in relation to the area of forest which produced it, promises to be materially increased by the Sihl Valley Railroad, whose construction in the near future will unquestionably enrich the whole valley through which it is to pass. It is not known to me what proportion of this amount, resulting as it does from the sale of fuel and manufactured wood, is derived from the mills as distinct from the forest; but undoubtedly their contribution is of importance. The centre of their activity is, of course, the saw-mill, where ten of the sixty horse-powers, which a turbine takes from the Sihl, go to drive a hand-saw, whose cut, of perfect smoothness and accuracy, is adjustable to the twenty-fifth of an inch and lies in a horizontal plane. The remainder of the power is consumed in the handle factory, whose principal machinery is American, a series of Excelsior machines, circular saws for various purposes, and four extremely simple contrivances for splitting the smaller kinds of firewood. Blacksmiths' and wagon shops—the Sihlwald manufactures nearly everything it uses—and a Boucherie apparatus, for the injection of wood with a solution of copper sulphate by hydrostatic pressure, complete the list. So successful has the injection plant been that telegraph poles, given by its means twice or three times the life they would have had without it, have been exported as far as Rome, and railroad ties, wood pavement, shingles, vine props and a variety of other articles prepared in the same way, have made a very handsome return to the management that was bold enough to undertake their manufacture.

The annual yield of wood, almost half of which is from thinnings alone, reached last year 377,023 cubic feet, an amount which may be taken as slightly above the average. The proportion of fire-wood is generally seventy-four per cent., yielding, however, but sixty-four per cent. of the total revenue. Wages, according to Herr Meister's admirable treatise on the Sihlwald, published in 1883, were at that time at the rate of a little more than half a cent per cubic foot for felling logs, and one dollar and nine cents per cord felled, split and stacked. This represents only from fifty to seventy cents a day; yet the workmen are happy and prosperous, as the statistics of the savings bank and mutual relief fund established among them by Herr Meister go far to show.

With an average stock per acre of 2,860 cubic feet, and the land estimated at \$140, the capital value of the Sihlwald is variously stated and decidedly hard to get at. Herr Meister's estimate, given to me last spring, was \$500,000. A calculation based on an assumed rate of interest of four per cent. makes it \$320,000, whereas three or even two and a half per cent. on investments is here often regarded as sufficient. Exact figures are not obtainable, from the nature of the case.

But the interest of the citizens of Zurich in the Sihlwald is far from being wholly centred in the substantial return which it makes to the city treasury. Their second interest lies in the qualities of a great city park, which it unquestionably pre-

sents. It has been the wise policy of Herr Meister to maintain throughout the forest a net-work of well-kept roads and paths, to place occasional benches along them, to keep the beauty of the landscape unharmed, and in general to make the Sihlwald thoroughly and pleasantly accessible. In so doing he has secured its future by demonstrating to the people the reality and value of their ownership.

The question naturally arises whether the multiform advantages to be derived from such a city forest in Switzerland might not be enjoyed in America. The factors which it involves cover too much ground to admit of discussion here, but this much may be briefly said: Were such a forest once in the possession of one of our cities it would not only afford a place of resort whose peaceful freedom would exceed in restful quality all that our present parks can give, but it would combine, under proper management, a steadily increasing revenue to the city, with an educational force and value such as, in the present state of forestry in America, would be amply sufficient to justify its existence. The value of the Sihlwald to the City of Zurich is great and unquestioned, but whether the system might be advantageously transplanted to America, local circumstances must go far to decide.

Nancy, France.

Correspondence.

The Evils of Grafting.

To the Editor of GARDEN AND FOREST:

Sir.—Your correspondent, Mr. S. B. Parsons (see page 350), is not quite so logical as usual in his replies to Mr. William Robinson's questions on the above subject. For example, Mr. Parsons tells us that "no intelligent or conscientious nurseryman will think, under ordinary conditions, of grafting a cion upon stock which suckers, or upon stock which is not closely related to it," and yet he fully bears out in his replies to the questions asked the statements that such errors are committed by nurserymen time after time. Mr. Robinson's American Weeping Willows and his dwarf *Pyracanthas* had both been grafted by nurserymen on coarse-growing stocks, both of which suckered badly, and the Quince stock used in the case of the *Pyracantha* could scarcely be said to be closely related to the cion. Again, we find even Mr. Parsons himself recording his testimony against grafting or budding, not only in the above two cases, but against the working or budding of Roses, which he does in these pregnant words: "I can see no reason why plants which take root readily from cuttings should be increased by grafting, and I yesterday found myself very impatiently rooting out some Tea Roses which I had imported from England, and which were budded and overgrown by the stock." The fact is that three-fourths of the direct evidence given by Mr. Parsons on page 350 is in perfect agreement with the opinions expressed by Mr. Robinson and held by myself.

Mr. Parsons says that my strictures upon and against grafting may be taken as "a reflection upon a large body of respectable men." I, in writing, like to state a case as definitely as possible, and the aphorism that "grafting is always a makeshift, and very often a fraud," is fully corroborated by Mr. Parsons having to root out his Tea Roses, and also by Mr. Robinson's difficulty with two hardy shrubs, Willow and Firethorn, respecting both of which Mr. Parsons thinks as we do, that they should not be grafted at all!

The fact is there has arisen a tendency to graft everything, as if there were some occult advantage in the mere operation of effecting a more or less perfect union. The old notion that a strong-growing or a vigorous-rooted stock would add strength and vigor to a weakly cion is utterly exploded by modern physiology. The converse of this—namely, the grafting of a vigorous cion upon a more slow-growing, weakly or restrictive stock—may in certain cases conduce to precocious fruiting, but certainly the same result could be more readily obtained by other and more simple cultural methods. An English gardener who visited Florida lately tells us that the grafted Orange-trees there fruit earlier than the seedling-trees, but that the latter are immeasurably superior in health, fertility and longevity. Dr. Wallace, in his chapter on "Acclimatization," in his latest work, "Darwinism," says that the eastern Orange-trees as introduced to Italy and increased by grafting, continued tender and unsatisfactory until the practice of rearing seedlings began. Again, even our greatest English experimenter and cultivator of fruit-trees, Thomas Andrew Knight, began to doubt the efficacy of grafting toward the end of his career.

I still believe that a vast amount of harm has been done to gardening by the fatal facility of grafting plants which, as Mr. Parsons himself shows, could be better and often cheaper

increased by other and more simple methods. It is not a question of what is easiest or cheapest to the nurseryman, but what is best from the general cultivator's point of view.

Grafting, even although it sometimes does afford facilities of increase, also acts indirectly in the very opposite way. For example, if a choice shrub or a fine fruit-tree is worked on a common stock, then the suckers are a source of trouble and loss, but were these desirable plants on their own roots suckers would become a gain. In a word, a plant grafted on a stock standard or half standard high becomes exceedingly difficult of increase except by grafting! This is a point worth bearing in mind in connection with this question, and looking at grafting from all points of view, I am convinced that we should have had better fruit-trees and better and healthier and more prolific varieties in our gardens to-day had grafting never been invented.

As to the delicacy of the Ribston Pippin Apple, I believe I am correct in saying that a sucker of the original seedling tree is still alive in the British garden in which it appeared a century or two ago. When Mr. Parsons talks of "inherent weakness of constitution" as a possibility in this case, it may be so or it may not. To find out if this delicacy and liability to canker is "inherent" or caused by unsuitable stocks, or grafting, Mr. Robinson has gone back to first principles, and has now a healthy little plantation of Ribston Pippins on their own roots, and I think every nurseryman more especially should experiment also in this direction, and while they keep on grafting stock, give the purchaser at least a chance of seeing with his own eyes a few specimens ungrafted. If I write and order a rare shrub or tree ungrafted and it is sent grafted on something else I submit I have a right to return it, just as I have to return a grocer coffee mixed with chicory, when I had expressly ordered pure coffee.

I have frankly stated my opinions on grafting after having seen and experienced a good many of its evils, and I am glad to know that my remarks have led to more careful methods of observation on this and kindred subjects on the part of amateurs and practical gardeners. This is a great gain since the old times when grafting was considered to be an unmixed blessing, and I hope that your Horticultural Experimental Stations in America will take up the subject and carry it further than any individual can possibly do.

In conclusion, I should like to allude to the seedling Apple-trees mentioned by Mr. Parsons as having sprung up over the older settled parts of your country. A glance at Downing's work will show how many of these are now established varieties, indeed most of your best fruits are different from ours. I presume the three Apple-trees mentioned by you on p. 352 are all seedling trees. The context seems to show that the first is so and the last and largest tree, in Washington County, is absolutely stated to be a seedling planted in 1791 or 1792. The trunk where it is smallest girths twelve feet two inches, and the largest branch girths seven feet. I should like to hear of a grafted Apple-tree a century old and of these dimensions.

Botanical Gardens, Trinity College, Dublin.

F. W. Burbidge.

[American nurserymen are aware that evils result from grafting when it is practiced without judgment, but they do not therefore condemn all grafting; nor will they believe that it is "always a makeshift." Indeed, it has been shown in these columns that grafting serves many useful purposes which cannot be attained so effectively by any other known method. Perhaps more seedling Apple-trees are grown in the United States for the purpose of obtaining new varieties than in all the rest of the world, but Mr. Burbidge does not need to be reminded that these varieties cannot be perpetuated by seed.—Ed.]

Periodical Literature.

IN the August number of *The Forum* is an article on "The Possibilities of Agriculture," by Prince Kropotkin, in which he attempts to show the fallacy of Malthus' theory that as population increases the new comers will find no room at the feast of Nature. It is hardly worth while to speculate as to what humanity will do when it begins to feel overcrowded, since that question is so remote that its decision may be left to our descendants. But it may not be out of place to give some of the examples which are used to illustrate the possible increase in the productive power of the earth under intensive methods. Thirty years ago twenty-two bushels of wheat to the acre was considered a fair crop in France, while the present average is, at least, thirty-three bushels on the same land,

and in the best soils the crop is considered good only when it yields from forty-three to forty-eight bushels, and occasionally as much as fifty-five and a half bushels to the acre. Experimental farms in central France produce annually over large areas forty-one bushels to the acre, and there are farms in northern France which yield year after year from sixty-five to sixty-eight bushels to the acre, and as much as eighty bushels have been obtained upon limited areas under special care.

At Whitley, England, from 77 to 110 tons of Beets have been grown on an acre, and in France for fourteen consecutive years, on the same lot of land, forty tons of fodder for ensilage—that is, the food of four cows at least—is obtained from an acre. It is somewhat rashly assumed, too, that Mr. Hallett, by a simple selection of grains, will soon obtain a wheat which will yield the yearly supply of bread for a full grown person on a score of square yards! Under high cultivation two and a half tons of hay in Flanders has been considered a fair crop, but when irrigated with pure water these meadows yield three or four times as much—that is, a money return of from \$120 to \$280 an acre is obtained from soil which formerly yielded only from \$16 to \$48 worth of poor hay; while below Milan the nearly 22,000 acres irrigated with water from the city sewers yield crops of from eight to ten tons of hay as a rule, while occasionally some separate meadow will yield the enormous amount of eighteen tons of hay to the acre—that is, the food of more than three cows for a year.

Proceeding to examples in horticulture it is stated that the Paris market-gardeners are able to pay \$126 rent to the acre and make a good living. What attracts market-gardening to the vicinity of great cities is the stable manure, and the value of this is not so much due to the richness which it adds to the soil as to the increased temperature which it supplies by fermentation. Early vegetables pay best and the soil as well as the air must be warm. But it is plain that this warmth can be obtained more easily by pipe-heating, so that a few years ago the Paris gardeners began to heat the soil by means of portable hot-water pipes. It is also stated here that the original fertility of the soil is of little consequence to the best gardeners, since the soil is always actually made, so that it is now a usual stipulation in the renting contracts that the gardener may carry away his soil, and when he moves to another plot he carries it away with his frames and water pipes and other belongings.

The Island of Jersey is a land of open-field culture, and yet it nourishes a population of two inhabitants to each acre and the early Potato crop returns more than \$300 to each acre planted. Besides this, cereals and grass are grown for cattle, and more than one cow is supported on each acre of grass-land. In addition to the enormous amount of dairy products exported, 1,500 milch cows a year are sent away, so that an agricultural produce to the amount of \$250 an acre of the entire surface of the island, including the rocks, is obtained.

The Island of Guernsey nourishes 1,300 souls to each square mile of soil, which is less productive than that of Jersey, but the land is given over to market-gardening and greenhouse culture. These greenhouses are seen all over the fields and on the steep slopes of the hills, the origin of this new departure being the production of grapes, which was started some thirty years ago. Five hundred tons of grapes are annually exported now, and yet the most important crops under glass are ordinary vegetables like Tomatoes, Potatoes, Carrots, etc. Three-fourths of an acre under glass and heated for three months in the spring yields some eight tons of Tomatoes and 200 pounds of Beans as a first crop in April and May, to be followed by two crops more in summer and autumn. In simple glass and plank shelters Pea plants cover walls in places for a length of a quarter of a mile and potatoes are dug in April at the rate of five bushels to twenty-one feet square.

Mr. Bashford, in the Island of Jersey, has vineries which cover thirteen acres, and the money returns from them greatly exceed those of an ordinary English farm of 1,300 acres. The last year's crops were twenty-five tons of grapes, eighty tons of tomatoes, thirty tons of potatoes, six tons of beans, (the last three April-crops), to say nothing of subsidiary ones. The cost of the houses is only \$2.34 to the square yard without taking into account the pipes, and all the work is done by thirty-six men. A thousand loads of coke and coal are all the fuel that is required. Besides these well constructed greenhouses, simple shelters which cost only ten cents a square foot often help to raise surprising crops ready for sale by the end of April. Altogether the glass house is no longer a luxury, and grapes will soon cost in England no more than the few pence they cost on the Rhine, because the labor in growing grapes in Northumberland, where a ton of coal costs but three shillings at the mouth of the pit, is much less than the

work which has to be done in carrying the soil up the cliffs of the Rhine to the height of several hundred feet and in attending to the vines there.

Prince Kropotkin gives no forecast as to the possible productive power of the earth when organic manures—that is, special liquids containing special microbes—are used in addition to chemical manures, and when science has discovered some economical way of obtaining nitrogenous fertilizers from the limitless supply of nitrogen in the atmosphere which surrounds the earth. But he makes a suggestion to American readers which it is worth while to reproduce:

"Suppose that instead of building at the Chicago Exhibition an Eiffel tower 1,000 feet high, a number of intelligent men should cover with glass houses, say, a hundred acres or more. Suppose they devote forty acres to art—I mean to flowers and to tropical vegetation—and the remaining sixty acres to the plainest vegetables and fruits, such as will be consumed by the ton during the exhibition. It will not cost one-tenth part of what the tower would cost, but it is sure to repay the expense. And—what is infinitely more important—it will make a complete revolution in the ideas of mankind as to what the soil is, and how it must be treated. It will stimulate invention in a field where it is most required; and it will be a new departure for the coming century."

Notes.

We have received from Messrs. Siebrecht & Wadley a flower of *Gloxinia* which is pure white, with no color-markings whatever. It is from one of their seedling plants and it seems to have great substance.

The annual *Gladiolus* show at the stores of Peter Henderson & Co. is now in progress and it is quite as interesting as it has been in former years. Besides the *Gladiolus* there is a varied display of French Cannas, Lilies and other summer blooming plants, with fancy *Caladiums*, Ferns and a large collection of well grown Palms. A tank full of choice aquatics seems to be the principal attraction for many of the visitors. The exhibition will remain open through Friday.

In the forest behind the Castle of Mereworth, Maidstone, stands a Beech-tree whose age must be more than 250 years, and which shows no indications of decay. The bole at three feet from the ground measures seventeen feet in circumference, and it only commences to branch at a height of twenty-two feet. The diameter of the crown is thirty yards. Dates cut in the bark about the middle of the last century, still clear and easily deciphered, show that it was a big tree then, and that it has expanded but little since.

An old periodical says of the poet Wordsworth: "He is fond of the Hollyhock, a partiality scarcely deserved by the flower, but which marks the simplicity of his tastes. He had made a long avenue of them of all colors, from the crimson-brown to rose, straw color and white, and pleased himself with having made proselytes to a liking for them among his neighbors." This was long before the days of the "æsthete" and his love for stiff "decorative" flowers. To-day a Hollyhock would not be called undeserving even of a poet's preference.

The *Gardeners' Chronicle*, in speaking of some flowers of *Fuchsia triphylla* which had been received from Mr. W. Dean, adds, "This old species, remarkable for its compact bushy habit, dark foliage, claret colored on the under surface, and its terminal racemes of orange-scarlet flowers, would make a good market plant. Cuttings struck last autumn, and grown on in an intermediate house in ordinary potting mould, are now flowering freely in the Birmingham Botanic Garden." In a recent description of these Birmingham Gardens in this journal it was stated that this plant there formed perfect specimens two feet through, and completely covered with clusters of long-tubed flowers. Since this *Fuchsia* was rediscovered by Mr. Thomas Hogg as long ago as 1873, it seems to have been slow in securing the attention it deserves.

In his article on the Yosemite, in the August number of *The Century*, John Muir speaks of the forest of Big Trees in Tulare County, which Secretary Noble has been asked to save from destruction: "But the finest block of *Sequoia* in the entire belt is on the north fork of the Tule River. In the northern group there are comparatively few young trees or saplings. But here for every old, storm-stricken giant there is one or more in all the glory of prime, and for each of these there are many young trees and crowds of eager, hopeful saplings growing heartily everywhere—on moraines, along water-courses and in the deep alluvium of meadows—seemingly in

hot pursuit of eternal life." That is, this is a true forest, with all the elements of continuous forest-life, and not merely a collection of ancient trees with no hope of a succession.

To illustrate the way in which we waste our forest-resources, Mr. Fernow writes in *Kate Field's Washington*: The poor state of Prussia, with a population nearly twelve times as dense as ours, must husband her resources closely to supply her wants. A first-class forest-administration is therefore among her institutions; and from its carefully collected experience we learn that forty-one cubic feet per acre per year is all the wood crop she can raise. Of this, forty per cent. is brush and such inferior-sized wood as no American would use. We may, then, accept an annual production of twenty-four cubic feet of wood per acre, over our whole forest-domain, as a reasonably large average figure. That is to say, there would grow only twelve billion feet, where we cut twenty billion, and eat into our forest-capital at the rate of eight billion feet yearly. Thus in progressive ratio are we despoiling our children's heritage.

The announcement of the death of John Ralfs at Penzance, England, on July 14th, at the advanced age of eighty-three, recalls the life and work of one who was formerly prominent in the botanical world, although it is now many years since he published anything on botany. His profession was that of medicine, and in his early days he practiced at Shoreditch. In 1839 he published a treatise on British Flowering Plants and Ferns; but his principal studies were on Desmids and Diatoms, and other low forms of Algæ, and in this field he was a recognized authority. He was the author of a considerable number of papers, especially on Desmids, most of which appeared in the *Annals and Magazine of Natural History*; but the work on which his fame now rests is "The British Desmidiæ," beautifully illustrated by Edward Jenner, which was published in 1848. This excellent work will always remain a classic on the subject. It is especially important to students of North American Desmids, since it includes the descriptions and figures of a considerable number of species collected by the late Professor J. W. Bailey, of West Point, by whom material was sent to Ralfs.

Experiments to test the relative value of steam and hot water for heating were conducted last winter at the Agricultural College of Michigan, and the tests indicate that for small green-houses hot water is more economical and more satisfactory than steam. In the month of December the steam-house had an average temperature one and a half degrees lower than that of the hot-water-house, although five tons of coal were consumed in the former as often as four tons were consumed in the latter. Maximum and minimum thermometers also indicated a greater variation of temperature in the steam-house than in the other. The records for other months were similar. During the month of April the two systems were compared in a different manner. The same amounts of coal were supplied to each house, and the result was that the hot-water-house was kept at a temperature seven degrees higher than that of the steam-heated house. Of course it cannot be proved that the most effective system of utilizing steam heat was used, and another kind of heater might reverse these results. But, on the other hand, it may be said that this test only corroborates the experiments made by Professor Maynard at Amherst.

Every reader of English novels knows of the "pot-pourri" made from rose-leaves which old ladies keep in china jars to perfume their drawing-rooms. The following recipe, recently given in the *Detroit Tribune*, may therefore be of interest: "Gather the roses in dry weather, remove the petals, and to a peck of fresh leaves add a good handful of salt. Let this remain five days, stirring up the leaves every day. When they appear moist add three ounces of bruised allspice and one ounce of cinnamon stick bruised. After this stands for a week, stirred daily from the bottom, put into a permanent jar one ounce of allspice, and add the stock layer by layer. Sprinkle between these layers one ounce each of cloves and cinnamon, two nutmegs, all coarsely powdered, some ginger-root sliced thin, half an ounce of anise-seed bruised, ten grains of fine musk, half a pound of freshly dried lavender flowers, two ounces of powdered orris-root and *ad libitum* cologne, rose or orange flower water, orange or lemon peel. Freshly dried violets, tuberose, clove pinks, or any other scented flowers may be added. Fine extract of any kind will enhance the fragrant odor, while fresh rose leaves, salt and allspice, made as at first, may be added when convenient. Stir the jar occasionally, leaving it closed except when the perfume is wished to odorize the room." Thin bags filled with this "pot-pourri" and placed in bureau drawers or linen presses impart a delightful fragrance to their contents.

City Improvement Societies.

ONLY a few years have passed since the first Village Improvement Society was organized, but scores of these associations are now doing good work in every part of the country in securing for rural communities more favorable sanitary conditions, improving roads and path-ways, beautifying public squares and the grounds about public buildings, educating the public taste, and in many other ways making country life more attractive and sat- isfying. There would seem to be little need for similar asso- ciations in cities where the government is more directly charged with the duties which these societies have assumed. There is a Board of Public Health to look after the city's drainage and general cleanliness. There are Park Com- missioners charged with the supervision of its public grounds. There is a Board of Works to look after the high- ways, and in many cases the planting of trees; and yet there is little question that an active association in every city which should charge itself in a general way with functions similar to those performed by the Rural Improve- ment Societies would help to supplement official action by directing it in proper channels and making it more effective. Organization is always effective by uniting the desultory efforts of individuals; and that much good can be achieved in the speciel direction indicated is proved by the effective work of the Metropolitan Gardens Association of London, the City Parks Association of Philadelphia and the Tree Planting and Fountain Society of Brooklyn.

A report of this last-named organization has just been received, and from it we learn that of the 70,000 trees now standing in the streets of Brooklyn a considerable portion have been planted under the auspices and at the sugges- tion of this Society. After it was formed, some eight years ago, many public meetings were held, circulars were issued, and articles calling the attention of citizens to the value of trees in city streets were published in the daily papers. But the work was carried on in still more practical ways. Various nurserymen were asked to fur- nish information as to the number of trees they had in stock of different varieties and the prices at which they could be obtained. As the time for planting approached

the Society secured a storehouse in which samples of trees from various nurseries were kept on exhibition, and suit- able persons were always in attendance to give informa- tion as to the proper methods of planting, the varieties most useful and the places where they could be obtained at the most favorable prices. When it was desired, the Society not only furnished trees at cost price, but sent skilled men to plant them and charged for the special ser- vice only the amount that they had paid for the labor. After the trees were planted instructions were given as to their care; devices for protecting them from horses and other dangers were explained, and efforts were made to create a feeling that the city trees were common property and that every citizen had a personal interest in preserving them. In order to properly educate the young, this Society urged the Legislature to pass an act for the encouragement of arboriculture, and this resulted in the appointment of an Arbor Day for the state, and in its celebration public exercises are conducted by the various school officers throughout the state and participated in by all the children of the public schools. Of course, this general work is but a small portion of what the Society is constantly doing. As an example of its special watchfulness, it may be stated that when some of the trees, notably the Maples, in the city were suffering from the ravages of an insect, a com- petent entomologist was called in to make a study of the cause and to report upon the best means for overcoming this evil.

Altogether there is no good reason why associations of this sort could not be made as helpful in the city as in the country. Without naming all the directions in which their influence could be exercised for good, it may be worth while to indicate one in particular, and that is in protecting public parks. It is not always, perhaps it is not generally, true that commissioners of city parks have any adequate appreciation of their true function. They cannot be trusted to repel the attacks constantly made on the parks; they often side with the assailants and organize attacks of their own. In this city, for example, it is constantly happening that city officials who would hardly assume to make plans for a monumental public building consider themselves per- fectly competent to design an urban park or change the design of one already made. It has never dawned upon them that one of these works is or ought to be as truly a work of art as the other. Only a few days ago the Mayor of this city suggested in an off-hand way, and yet in his official capacity, that the entire system of walks and drives in Central Park should be remodeled. He was troubled by no doubt that his plan would be infinitely superior to the original one, or that he was perfectly qual- ified to direct such an undertaking. Similar attacks upon the integrity of our parks, efforts to pervert them from their highest use, and even attempts to obliterate them or to confiscate them to some alien use, are happening every year. Central Park has been saved as by fire, simply be- cause there has been intelligent opposition to its destruc- tion made in a few newspapers. These assaults will probably grow more frequent and more urgent as popu- lation presses about it more densly, and the time may come when a well-organized defense will be needed to keep its woods and meadows from being utterly trampled out or covered with brick and stone. A voluntary association which would, in addition to other duties, devote intelligent attention to the preservation and proper management of parks could find an ample field for labor in every consid- erable city of the Union.

Just a year ago we published a letter from Mr. Charles H. Shinn (vol. ii., p. 398), in which it was stated that Colonel J. B. Armstrong proposed to dedicate 400 acres of magnifi- cent Redwood forest to public use forever. It was there said that this piece of primeval wood was of almost unique value, since it has never been touched by the axe nor has it been pastured. It shows the growth of the Redwood in every type; in single trees, in clumps of twos, threes, fours

and so on up to family circles of ten or twelve about the roots of some giant of an earlier generation. The very side-sprouts, which grow up from the base of these Redwoods, are as large here as timber-trees in other countries. One of the trees which Mr. Shinn measured was forty-seven feet in circumference and 325 feet high.

From a late number of the *Cloverdale Reveille* we learn that Colonel Armstrong has decided not to present the state with this tract of Redwood, nor does he intend to give it to any particular municipality, but to trustees, for the use of the people for all time. The Board will be constituted perhaps as follows: The Chairman of the Board of Trustees of the Golden Gate Park of San Francisco, the landscape-gardener of Central Park, the Chief Justice of the Supreme Court of California and a local trustee in the county. These gentlemen will have the power of appointing their successors, and they will be hampered by few restrictions in the deed of trust. One condition will be that none of the timber is to be cut. Another is that the park shall not be a place of encampment, for fear of fire, and that it shall only be visited by daylight. This magnificent tract lies in Sonoma County, and is accessible by rail from San Francisco, which is only seventy miles distant, and it is the last considerable tract of Redwood in this region or so near the city. Of course the forest is not exclusively Redwood, for these trees are mixed with Laurels and Oaks, sometimes in a compact wood and again in open order, with occasional grassy openings.

It is probable that this report is incorrect in one particular, and that is in regard to arrangements which are said to be in preparation for propagating strange plants, flowers and shrubs to be used in bordering the drives and otherwise ornamenting the giant grove. No doubt Colonel Armstrong appreciates his forest so thoroughly that he will not think of improving it by tricking it out with any exotic finery. He means to preserve it for posterity as a Redwood forest and he will hardly allow its grand expression to be trifled with by any attempts at decoration.

A Fine Bur Oak.

WE published last year (ii., 500) an illustration showing the stem of a remarkably fine specimen of this tree grown on the rich alluvial lands bordering the river-bottoms of southern Indiana, where this species attains its greatest height and girth of stem. This particular specimen had grown in the midst of the forest, thickly encompassed by other trees which had forced an upright development of stem and prevented the great spread of branches characteristic of this and other species of the Oak when these trees find the room and light essential for the full growth of their lateral branches. Wide-spreading Oaks are never met with in the dense forest, although they abound in the north-west in the region which separates the heavy forests of the eastern part of the country from the midcontinental prairies. These intermediate regions, covered with an open growth of Oak-trees, are called Oak-openings. The sparseness of the timber and the prevalence of Oaks, which resist better than most other trees the effects of constant burning, is due, no doubt, to the fires which constantly swept over this whole territory before the advent of white settlers. These fires made the prairies what they are and restricted the forest-growth on the debatable middle ground to the edges of sloughs and other depressions in the general surface of the ground where occasional trees were able to escape the effects of fire and grow to a very large size.

The Bur Oak (*Quercus macrocarpa*) is one of the common trees of the Oak-opening region, where it grows sometimes to noble size. A portrait of one of these large trees appears in our illustration on page 407. It shows the habit and appearance of this tree when it is allowed full opportunity for unimpeded growth in all directions.

This specimen is known as the "Cravath Tree," from the fact that it stands on the farm of Mr. Miles G. Cravath,

near the town of Whitewater, Wisconsin. The trunk girths at the ground eighteen feet and six inches. Three feet higher it is twelve feet three inches, and the beautiful cylindrical stem and ponderous limbs are perfectly sound, the tree being still in perfect health. The age of this great Oak can, of course, only be guessed, but it must have been a remarkable specimen in a region of fine trees long before a white man first floated over the surface of the limpid waters of the upper Mississippi.

We are indebted to Mr. Edward Salisbury, President of the State Normal School at Whitewater, for the photograph from which our illustration has been prepared.

The Florida Spruce Pine.

THE littoral belt extending from the alluvial lands of the Mississippi River eastward to the neck of the Peninsula of Florida presents no essential difference in climate or soil, or in the general features of vegetation throughout its entire length. Meteorologically it all belongs to one province. The line of sixty-eight degrees mean annual temperature follows the northern border along the thirty-first parallel of north latitude, and the isotherm of seventy-two degrees follows the sea-shore. The mean annual precipitation between these limits varies from forty-eight to fifty-four inches, showing but slight differences in its distribution throughout the year. Highly silicious deposits of stratified drift cover its surface, almost everywhere making sandy and gravelly soils or light sandy loams. The flat coast plain, intersected by large bays, and smaller inlets surrounded by marshes, is fringed along its shore by hillocks of loose and often drifting sand. The Long-leaved Pine or Cuban Pine form very open forests, which cover a large part of the plain. The damp, sandy soil of these flat-woods, devoid of surface drainage, is covered with a dense carpet of Cyperaceous plants, *Rhynchospora*, *Scirpi*, *Fuirenas*, *Eleocharis*, and numerous species of *Xyris*, *Eriocaulon*, and *Sarcenias*. Their monotony is relieved by groves of Live Oak and Wax Myrtle on the sands of the sea-shore and the more varied tree growth of the richer spots of the swampy depressions. Magnolias, Laurel Oaks, Water Oaks, Sweet Gum and Black Gum are the most prominent on the hammock-land, while the Bald Cypress represents the water-soaked banks of the rivers and their estuaries.

One who travels this coast from west to east is struck by the successive appearance of plants which are never or very rarely met with in the section left behind. If he leaves the eastern shore of the Bay of Mobile his attention is constantly directed to the plants which he has never encountered in the coast region between the western shore of the bay and the Mississippi delta. After crossing the extensions of the sea which intersect this coast, and entering the basins of the great streams which empty into them, he is surprised by the sudden appearance of plants not observed before, most of them becoming more frequent as he approaches the region which discharges its waters into the Atlantic. It would seem that while the wide bays of this coast, with the river basins connected with them, form the only obstacles to the general diffusion of plants over the littoral region of the eastern gulf states, yet to many species which are found on the South Atlantic seaboard these obstacles prove insurmountable, and absolutely prevent their spread toward the west. It would seem also that other plants whose centre of distribution lies toward the western confines of this belt are prevented by the same difficulties from making any progress toward the east. At another time it may be of interest to give instances of this restriction of different species to given limits, instances which cannot but excite interest in the problem of plant distribution throughout a region in which the same climate, soil and topographical features prevail.

Among the forest-trees which one would observe in connection with this distribution of plants, *Pinus clausa*, the Florida Spruce Pine or Sand Pine, would occupy a prominent place. Among the Pines of the southern United States this species is confined to the narrowest limits. It is found from the western boundary of Florida to Key West, where it was observed by Professor Sargent, and along the eastern coast of the peninsula, on the rolling uplands to their termination in the lower part of Volusia County, in the flatwoods and swamps of the further south. This Pine is strictly confined to an arid sandy soil; it flourishes on the dunes of pure white drifting sands which fringe the shore, where its roots often fail to obtain a firm hold, so that it often succumbs to the force of storms, and it is seen bent low in the direction of the prevailing

wind, and sometimes is entirely prostrate. On these sterile wastes the tree is rarely more than twenty or twenty-five feet high, while on the dry ridges with a more solid soil, as near Pensacola, it attains the dimensions of a medium-sized tree, and on uplands of the best quality, where the apparently barren ground is underlaid by a subsoil of the fertile tertiary marls, it arrives at the dimensions of a stately forest-tree, associated with mighty Magnolias, large upland Hickories (*Hicoria glabra* and *H. tomentosa*), Live Oaks, Laurel Oaks and Post Oaks.

On these fertile upland hammock-lands, as found prevailing back of Halifax Bay, the Sand Pine arrives at its best development. Trees over seventy-five feet in height and fully twenty-five inches in diameter are frequently seen here. In this best state of its growth the tree somewhat resembles the Spruce Pine, *Pinus glabra*, with which it is frequently confounded by the settlers.

By the structure of the wood as well as by morphological characters, this species forms, with *Pinus glabra* and *P. echinata*, a natural group of southern distribution. The leaves are in twos, with a short, deciduous sheath from half an inch to two inches or more in length, a half line wide, slender, flexible, concave and slightly keeled on the upper side. The cones are sessile, horizontally inserted during the first year and strongly reflexed as they reach maturity during the second year. They are from two and a half to nearly three inches long and from one and three-fourths to two inches wide when open. The exposed portion of their scales, with a slightly prominent umbo, is crowned by an erect, short and blunt prickle; they remain on the tree closed for several years. The bark of the young trees is rather smooth, roughish in those of fuller growth, furrowed and divided in square scales. The young shoots are tender. At all seasons and stages of growth, this Pine is readily distinguished from the Scrub Pine (*P. inops*) by the less rigid, more slender foliage of dark green, and from its allies by the ashy gray, reflexed, rigidly closed cones. It produces its fruit abundantly, and almost without failure, season after season.

The wood of this Pine is of a yellowish color, the broad sapwood of a lighter tint; it is soft, easily worked, but wanting in strength and elasticity, and is not durable. Hence as a timber-tree it is regarded as of no importance. The old trees of stunted growth from the sand-dunes along the seashore, with a wood of close grain and of greater toughness, are used for masts for the boats of fishermen and other small craft. As pointed out by Professor Mayr, this tree will in future be undoubtedly of importance in the forestry of the states of the lower south, when the reforestation of the denuded sandy Pine barrens, immense in their extent, is demanded by necessity.

Mobile, Ala.

Carl Mohr.

Improving Plants by Crossing.

WHILE it must be confessed that the science of plant breeding is far too little understood, one who has made a study of the history of the artificial development of varieties can hardly escape the conclusion that much more successful results have followed the intelligent crossing of varieties than the indiscriminate growing of seedlings, even though the number of plants by the latter method was very much larger. This is what we should naturally expect, and is in perfect accord with the experience of animal breeders. In the mere sowing of seeds, without reference to their inherited qualities, we are aiding Nature by the hand, but in the sowing of intelligently crossed seeds, we are aiding her by both the hand and the mind, and the mind is altogether the most potent agent.

The growing of seedlings is very generally practiced by amateurs to a greater or less extent. In so far as the motive is a hope of securing improved varieties the result is almost always disappointing, especially in the more highly domesticated plants. On the other hand, those who have sought to combine in a new sort, by crossing, certain specific characters possessed individually by others, have in very many cases been successful. Indeed, from the experience of the past, it seems almost safe to say that any two desirable qualities possessed by different varieties of a species may be combined by crossing. This result could not always be reasonably expected in a single attempt, and it is possible, also, that there are laws of correlation which would prevent the union of certain characters. But, in our present knowledge, the chances of securing improved varieties by crossing are so much greater than by selection from seedlings of unknown inherited qualities that the latter method is not at all to be recommended where the former is practicable.

The phrase, "intelligent crossing," has been used advisedly. The indiscriminate crossing of varieties is little more likely to

result in progress than the indiscriminate growing of uncrossed seedlings. We should know definitely just what characters we desire in our prospective variety, and should select our parents with the greatest care. Mr. Darwin made the statement, quoted here from memory, that "not one person in a hundred possesses the accuracy of eye and judgment necessary to the most successful breeder." If this is true of animals, it is certainly in a measure true of plants. A thorough knowledge and a careful study of the characters of the parents is indispensable to the highest success, and the same discriminating care is necessary in the fixing of the variety after the cross is secured.

A second argument in favor of crossing as a means of securing improved varieties is the fact that the crossing stimulates variation to a remarkable degree, so that we have not only a chance of combining certain definite qualities of the parents, but also of securing an almost infinite number of other combinations. It certainly is true that the variations resulting from a cross are not necessarily limited to the visible qualities possessed by the parents, but that entirely distinct types may appear in the offspring. If the aim were simply to secure variation, the best known way to accomplish this would be to cross the most widely differing individuals that could be obtained.

It is greatly to be desired that the subject of plant improvement should receive more attention from horticulturists. No other department of horticultural experiment offers a more inviting field. Fruits, vegetables and flowers are in themselves priceless possessions, and the introduction of varieties that make possible better or cheaper fruits, vegetables or flowers than we already have is certainly an end worth striving for. He who produces Wilson Strawberries or Concord Grapes for the market does his fellow man a transient good. But what shall we say of him who originated the first Wilson plant or the first Concord vine? He may be said to have made possible the supplying of the masses of our population through all the future with a delicious and wholesome fruit that had before been only within the reach of the comparatively wealthy. Surely neither statesman nor inventor has conferred upon his fellows a greater boon.

Foreign Correspondence.

Messrs. Backhouse & Sons' Nurseries at York.

THE Holgate Nurseries, in the ancient city of York, are amongst the most famous of plant establishments in England. They have been in existence over a hundred years, and are now managed by the third generation of the Backhouse family. The first was the missionary nurseryman, James Backhouse, who combined with business capacity and a love of plants zeal in the spread of Christianity, which for ten years he taught to the natives of the Cape and New Zealand. He collected plants and sent them home to his nursery at York, amongst the most notable of his collections being numerous Filmy Ferns, which in the York nurseries have been and still are cultivated with marvelous success.

The nurseries have, of course, grown in extent and importance since his time, and they are now generally acknowledged to be amongst the best managed and richest known. The grounds consist of about one hundred acres, and the in-door department of some forty houses, mostly large and of modern design. Four broad walks run parallel from one end of the nursery to the other, and they are flanked by broad borders filled with the choicest of trees, shrubs and herbaceous plants. The arrangement is artistic, the most striking of the plants are conspicuously labeled, and every plant looks so perfectly at home that a walk through these borders alone is delightful to any one interested in gardening; and what a wealth of noteworthy subjects he will see, no matter at what season he goes. Conifers and other evergreens, ornamental at all times, groups of Roses, Spiræas, Ericaceous plants of all kinds, Syringas, etc., with hundreds of the best of herbaceous plants suitable for border planting. Long before the mixed border and a passion for hardy herbaceous subjects took possession of English horticulturists, the York nurseries had an unequalled collection of everything that was good and choice amongst alpine and herbaceous plants.

Stretching away from the borders are the long rows of fruit-trees, forest-trees, conifers and so on, all in good order, with a well-cared-for air about almost every plant. Many nurserymen lack the knack of making an attractive display or show an indifference to it which must surely be a mistake.

The rock garden is a great feature in this nursery, and since about 1,500 tons of rock and £2,000 in money have

been expended in constructing the rockery its extent may perhaps be realized. But, besides stone and money, a considerable amount of art is needed ere a good rock garden can be formed. The best judges say that there is no finer arrangement of stones and plants in England than this in the York nurseries. Huge masses of stone are piled up cliff-like in some places, and are backed by suitable trees, whilst from another point the stones are arranged to represent a glacial slip and their summit is clearly defined against the sky. The effect is delightfully deceptive, for whilst the actual height of the stones is only about twelve feet above the ground-level it appears to be at least twice that height. Winding around and amongst the piles of rock are streams, or small clear pools of water containing Nymphæas and other aquatic plants. In boggy nooks one sees healthy examples of *Darlingtonia*, *Sarracenia*, *Rodgersia*, *Todea*, and other moisture loving plants. Ferns there are in abundance, whilst *Cistuses*, *Campanulas*, *Ourisia*, *Cotoneasters*, dwarfed Pines, *Ramondia*, *Daphnes*, *Genistas*, Bamboos, Pinks of all kinds, *Veronicas*, *Saxifragas* innumerable, *Eurybias*, the North American *Cypripedia*, with many other suitable plants, all combine to make a picture such as cannot be seen elsewhere except in the Alps of Switzerland. No plant that is suitable is omitted, and the consequence is that visitors are enabled to see for themselves the position best suited to each plant both as regards its safety and effect in arrangement. There can be no doubt that this rockery has been the cause of many other rock gardens being formed by English horticulturists. The delights of this department of gardening are supreme; no ugly pots, no stiff stages, very little of the watering pot or abominable flower-stake, but instead every plant looking quite at home in its nature-like surroundings, and so happy as to require very little attention. Then there is constant change, infinite variety and perfect enjoyment whilst working amongst or inspecting them. A great deal may be said in favor of the rock garden, but it must be properly made and carefully planted at the outset. Mere heaps of stones with a handful of soil here and there in the crevices and plants stuck in anyhow are not rock gardens, but only a source of disappointment and disgust.

The rock garden at York is the show-room for the herbaceous and alpine plants, of which the collection is exceptionally rich in variety and extent. Whilst some nurserymen send collectors to bring home Orchids, the Messrs. Backhouse send annually to the European Alps their superintendent of the herbaceous department, who collects and notes the natural conditions of all the choicest and best plants.

In the houses there are, of course, Orchids in endless variety. *Cattleyas* and *Lælias* are grown in thousands,—well grown, too,—and that in houses for which the thinnest muslin shading only is used even in the sunniest weather. The Messrs. Backhouse were among the first to prove that many Orchids thrive much better when scarcely shaded even in midsummer, than when shaded heavily, as is usually practiced. Mexican Orchids were in splendid health, and the *Cattleyas* were pictures of vigor at the time of my visit.

Catasetum Bungeorhizii is largely and well grown in a moist warm house. And hereby hangs a tale. Last winter a plant of this Orchid was accidentally kept moist by a roof-drip, and this plant wintered better, grew more vigorously and flowered more freely than those which had been dried off. I have myself proved that some *Catasetas* grow and thrive if kept in a moist house all the year round. It may be unnatural, but it succeeds nevertheless.

Cattleya gigas, *C. aurea* and *C. Dowiana* have flowered extremely well, the result of growing them in baskets suspended close to the ventilators in the top of a span-roofed house and scarcely shaded. There are *Cypripediums* of almost every kind, which is saying a great deal, seeing how very numerous the kinds are now. *Dendrobiums* are well grown and numerous represented; *Cœlogynes*, rare as well as popular species, were also full of vigor. I might run through the whole catalogue of garden Orchids and say with truth that they are almost all grown well in the York nurseries. The best and rarest are represented. Such fine Orchids as *Odontoglossum Harryanum* are grown in large quantity. The *Disas* were mentioned in last week's issue, but I may note here some good examples of *D. racemosa*.

Hard wooded plants are in favor with Messrs. Backhouse, whilst such choice greenhouse plants as *Rogeria gratissima*, *Luculia gratissima*, *Daphne Indica*, *Lapagerias*, *Asparagus decumbens*, a most elegant plant when grown in hanging baskets, Japanese *Rhododendrons*, *Pleroma elegans*, are grown in quantity.

In the stoves one may find all the popular favorites, besides many that are unknown in the majority of gardens—for Messrs. Backhouse have a taste for other plants than the big flowered

and the gaudy. *Adamia versicolor*, a cousin of the *Hydrangeas*, was in flower; treated as a stove plant it apparently blooms freely, whereas in a greenhouse it grows well but does not flower. It has large heads of bluish lilac flowers, not unlike those of a *Sonerila*; the plant is about a foot high. *Combretum purpureum* was a cloud of bright crimson on the roof of one of the stoves: *Sonerilas*, *Bertolonias*, *Ouwirandra fenestralis*—these I noted as being unusually well managed.

Ferns are a specialty in these nurseries. Nowhere, not even at Kew, is there so rich a collection of Hymenophyllums, Trichomanes and Todeas, collectively known as Filmy Ferns. An underground rockery of considerable size is entirely planted with them, and Fern connoisseurs enter it with feelings of delight and admiration. Only the favored are allowed to see it, but it is worth going a long way and taking a good deal of trouble to see. There are besides two houses entirely filled with these delicately beautiful Ferns, the rarest and choicest species being represented by large, well furnished specimens, some of which are at least twenty years old. Few people grow these Ferns, because, as a rule, beginners fail with them. An hour's neglect will probably work mischief that it will take years to undo. But when once their requirements are understood they are very easy to cultivate. The famous Cooper-Forster collection, now at Kew, was formed by a surgeon, and cultivated by him for many years in a house built against the window of his surgery in Grosvenor Street, right in the heart of London.

A large house is arranged inside like a natural fernery, with rockery and water, and is planted with all kinds of tree and other Ferns. *Gleichenias*, beautifully grown and numerous in kinds, almost fill another house, whilst others contain a large collection of tropical Ferns in beautiful condition.

York is a little out of the ordinary track of the visitor interested in gardening; but no American who finds delight in inspecting a well kept garden, rich in rare and beautiful plants, should visit England and not see the nurseries of the Messrs. Backhouse at York.

Visitor.

New or Little Known Plants.

Rosa multiflora.

THIS species is an old inhabitant of the Arnold Arboretum, where it was raised from seed sent by Max Leichtlin in 1874. It was first made known by Thunberg, who discovered it in Japan, and published the first description in his "*Flora Japonica*," printed in Leipsic in 1784. It has only been known, however, in a living state in recent years, the earliest description of it as a garden plant appearing in the *Revue Horticole* for 1876, where it is stated to have been introduced into France about 1862 by André Leroy of Anger, who obtained it from China.

*Rosa multiflora** is a vigorous plant with stout branches eight or ten feet long, recurved above the middle, and forming a dense mass of brilliant foliage, which reaches, when the plant is abundantly nourished and allowed free room for full development, a breadth of twelve or fifteen feet. The branches are stout, more or less zigzag, glabrous, light green, destitute of prickles, and armed with stout, flattened, recurved spines. The leaves are six or seven inches long, unequally pinnate, with stout pubescent petioles and conspicuous, deeply cut, comb-like stipules. The leaflets are distinctly petiolulate, ovate or obovate, the apex often contracted into a slender point, and are conspicuously and sharply toothed above the middle; they are dark green and lustrous on the upper surface, paler and slightly puberulous on the lower, especially along the stout midrib. The flowers are produced in axillary and terminal widely-branched corymbs, composing a pyramidal, rather one-sided, terminal panicle eight or ten inches long and four or five inches broad, the slender branches covered with scattered hairs. The flowers† are an inch across when expanded, with ovate-lanceolate, entire, pointed sepals, pubescent on the outer surface, deciduous

*Thunberg, "Fl. Jap.," 214.—Franchet et Sevatier, "Enum. Pl. Jap.," i., 134.—Crépin, "Bull. Soc. Bot. Belg.," xliii., 250; xviii., 278.—Forbes & Hemsley, *Jour. Linn. Soc.*, xxiii., 253.—*Bot. Mag.*, t. 7119.

†*R. polyantha*, Siebold et Zuccarini, "Fam. Nat. Pl. Jap.," i., 20.—Carrière, *Rev. Hort.*, 1876, 253, f. 49-53.

‡ In the recent figure of this plant in the *Botanical Magazine* the petals of some of the flowers are represented as pink, and in others as faintly shaded with pink. In all the plants raised in the Arboretum they are pure white.

from the fruit, and half the length of the pure white obovate petals, which are deeply lobed at the apex. The ovaries are villose, the long, slender, exserted styles cohering into a column. The fruit is long-stalked, elliptical, a quarter to half an inch long, with obtusely-angled, slightly pilose stones.

has been introduced into gardens for many years. It may be grown either as an isolated specimen on the lawn, or it may be planted on the margins of shrubberies or on rocky banks, for which purpose the pendulous habit of the branches admirably adapts it. It may be used, too, as a

Fig. 51.—*Rosa multiflora*.—See page 404.

Rosa multiflora is exceedingly free blooming, and toward the middle of June the plants are covered with the great clusters of Blackberry-like, sweetly fragrant flowers, in which the golden-colored anthers make a charming contrast with the snowy white petals. It is extremely hardy; it grows rapidly, and, where sufficient room can be found for it, it is altogether one of the most desirable shrubs that

hedge plant in the manner that the Cherokee Rose is used in some parts of the southern states.

There are two forms of this plant in the Arboretum, the one which appears in our illustration, and a plant received from Europe as *Rosa polyantha*. This is less vigorous than the other form; the stems are shorter, the flowers are smaller, and appear about ten days earlier. The plants

sometimes suffer in severe winters, and altogether it is the less beautiful and desirable plant of the two.

Rosa multiflora produces seed in the greatest profusion. This germinates readily; and plants may be raised also from cuttings or by layers.

The double-flowered form of *Rosa multiflora* was introduced into England as early as 1804 by Mr. Thomas Evans. It is known as the Bramble-flowered Rose, and is not rare in gardens, where many varieties have been cultivated at different times. The variety *Platyphylla*, which I do not know in any American garden, was described by Lindley, who published a figure of it in the *Botanical Register* (t. 1372), and who called it the most beautiful of all climbing Roses. He noticed, however, that the stems suffer sometimes in winter unless protected.

The results obtained by European rosarians by crossing *Rosa multiflora* with different forms of *Rosa Indica* and of *Rosa semperflorens* are seen in the so-called Polyantha Roses, which have of late years attracted considerable attention. These are not hardy here in the open ground, but Mr. Dawson has obtained a hybrid by crossing the Japanese species with various dark-colored Hybrid Perpetual Roses which is exceedingly promising. The plants obtained by these crosses are hardy, with good foliage, and produce clusters of small, dark-colored, highly-scented flowers. These experiments, although they have not been carried on during a sufficient period to be conclusive, are highly suggestive, and promise at least, a new race of hardy climbing Roses of peculiar beauty and interest.

C. S. S.

New or Little Known Orchids.

ODONTOGLOSSUM × LEROYANUM, Castle.—This is a most interesting artificial hybrid, raised in the collection of Baron Edmond de Rothschild, at Amandvilliers, near Paris, by M. Leroy. It was obtained about five and a half years ago from *O. crispum*, crossed with the pollen of *O. luteo-purpureum*, between which species it is quite intermediate. It is interesting because it is the first artificially raised hybrid *Odontoglossum* which has flowered, and also because it proves the parentage of *O. × Wilckeanum*. That plant has always been considered a natural hybrid between the two species in question, and *O. × Leroyanum*, though perhaps distinct enough horticulturally to retain the name, is quite identical from a botanical point of view.—*Gardeners' Chronicle*, June 7th, p. 704.

ZYGOPETALUM JORISIANUM, Rolfe.—A very distinct and handsome species, belonging to the section *Euzygopetalum*, but with a three-lobed, fimbriate lip and fimbriate column-wings. The lip is cream-white, with a broad yellow margin to the side lobes, and a purple crest, while the segments are green, heavily marked with purple-brown. The habit is somewhat like *Z. intermedium*, but the pedicels are much longer. It was introduced by M. Bungeroth from Venezuela, for the Society "L'Horticulture Internationale," of Brussels.—*Gardeners' Chronicle*, June 7th, p. 704.

CALANTHE × MYLESII, Williams.—This is a hybrid raised by Mr. Myles, of Ryde, Isle of Wight, between *C. vestita nivalis* and *C. × Veitchii*. There is, however, little trace of the latter in the plant, which bears pure white flowers like *C. vestita* in shape, with a lemon-yellow throat to the lip.—*Warn. and Will. Orchid Album*, ix., t. 402.

CATTLEYA LABIATA, Lindl., var. WAROCQUEANA, Rolfe.—This is one of the numerous forms which botanically are grouped under the comprehensive term, *C. labiata*, Lindl. It is very variable, and its relation to the other forms of this beautiful group is not yet clearly made out, though it is supposed to be a distinct geographical variety, in the same way as are *C. Mossiae* and *C. Trianae*, and others. It is said to be from a new district. It is being distributed by the society "L'Horticulture Internationale," of Brussels, as *C. Warocqueana*, Linden, under which name it was awarded a diploma of honor at a recent meeting of the Orchidénne of Brussels.—*Gardeners' Chronicle*, June 14th, p. 735.

CATTLEYA × INTRICATA, *Rchb. f.*, var. MACULATA, Rolfe.—A very pretty variety, with many rosy purple spots on the sepals and petals. It was collected on the mainland of Santa Catharina, Brazil, and is now in the collection of Mr. Malcolm Cook, of Kingston Hill. It is evidently a natural hybrid between *C. intermedia* and some form of *C. guttata*.—*Gardeners' Chronicle*, June 21st, p. 763.

CYPRIPEDIUM × AYLINGI, Castle.—This is a very beautiful hybrid, raised by Mr. Ayling, gardener to Mr. A. J. Hollington, of Enfield, from *C. niveum* fertilized with the pollen of *C. ciliolare*. The plant is very similar to *C. niveum* in habit, though the shape of the segments is modified in the direction of *C. ciliolare*. The lip is pure white, and the segments white with numerous dots of light purple, which are arranged somewhat in lines. It was awarded a first-class Certificate by the Royal Horticultural Society on June 10th, and a Botanical Certificate by the Royal Botanic Society on the following day.—*Journal of Horticulture*, June 12th, p. 480, Fig. 74; *Gardeners' Chronicle*, June 14th, pp. 747, 748; June 28th, pp. 792, 797, Fig. 131.

CYPRIPEDIUM × VIPANI, Rolfe.—Another very beautiful hybrid in the way of *C. Aylingi*, though quite distinct. It was raised in the collection of Captain Vipan, Wansford, from *C. Philippinense* fertilized with the pollen of *C. niveum*. As in the last, the lip is pure white, though more compressed laterally, while the segments are narrower, white, the dorsal sepal with eleven and the petals each with nine longitudinal stripes of bright purple. It is strongly stamped with the character of *C. niveum*, as indeed are all the hybrids which have this species for one of the parents.—*Gardeners' Chronicle*, June 28th, p. 792.

R. A. Rolfe.

Cultural Department.

Notes on Shrubs.

CONSIDERING their value as ornamental flowering plants and their habit of blooming when comparatively few other woody plants produce blossoms, it is surprising how extremely rare the hardy Heaths and Heather are in American gardens. This is the more remarkable when we think how much these plants are prized by many of the immigrants from Britain and the efforts which many of them have made to introduce their favorites from their native homes to the new, rich soils of this country. In a comparatively few cases the importations seem to have been successful. This is attested by the little patches of Heather which have occasionally been found in the older settled parts of the country along the Atlantic seaboard. Whether all the Heather in the localities where it has been found in Massachusetts, Maine, Nova Scotia and Newfoundland has become naturalized since the colonization of the country by Europeans, may remain a doubtful question; but the origin of several of the so-called wild patches has been clearly traced to the care and enthusiasm of some Scotch or Irish settler.

One reason why so many failures have occurred has no doubt been due to conditions unfitted to their growth and best development to which the plants have been introduced. The severity of our winter climate and the general necessity of some protection is also against them. Much of our heavy clay soil is unsuited to them, and it seems, as a rule, that they degenerate and die where there is much limestone or lime in the soil, unless a spot is specially prepared. In such cases the bed should be composed of peaty soil or leaf-mould mixed with about a third or more of sand, and it should be at least a couple of feet deep. The best success will result where the plants have fairly equable, but not too much moisture. Although the Heather will grow in shady places, the best specimens will be produced where there is plenty of light and air. Artificial propagation from seed is slow and troublesome, and the plants are more easily grown from cuttings or layers. By the last methods, also, any particularly free flowering or otherwise peculiar plant may be indefinitely perpetuated. In reproducing from cuttings the ends of the growing shoots are taken off and placed in sand and covered with glass until roots are formed. Where a plant is already established, however, it is much easier to propagate a few plants from it by layers. Wherever a spreading stem becomes slightly covered with soil it in time produces roots, and as soon as these are sufficiently numerous the new plant may be severed from the parent and safely transplanted.

For our northern gardens the most valuable of the Heaths is the common European Ling or Heather (*Calluna vulgaris*), both on account of its greater hardiness and also because there is quite as much variation in the form and color of its flowers as in any other hardy species. Besides the purplish red flowered type there are varieties or forms with deeper or paler colored flowers and some that are pure white. A very pretty and interesting form has large double rosette-like flowers. Plants which vary from the type in habit are generally not so desirable for garden culture. One or two very dwarf or compact forms are quite pretty, and make curious little tufts, but this diminutive habit does not seem to be accompanied by fine flowers. It is best to renew these and most of the other

Heaths every four or five years, for, although the plants live for a very much longer time, the old stems give them a straggling appearance. There is a good deal of difference in the time of flowering of different plants of Heather. Blossoms are often produced early in July, but generally in this latitude the plants are in the best flowering condition in the first and second week of August.

The Cornish Heath (*Erica vagans*) is much less hardy than the common Heath, and requires more protection to be

averaging about a quarter of an inch in length, are borne in close terminal clusters of from eight or ten to fifteen or twenty. The first flowers open about the middle of June, and the best flowering period is in the early part of July, but blossoms are freely produced throughout the month, and a few still remain when the two preceding species are in their most showy condition in early August.

The little Gray or Scotch Heath or Heather (*E. cinerea*) requires more care and frequent renewal of the plants in order

A Bur Oak (*Quercus macrocarpa*) in Wisconsin.—See page 402.

equally satisfactory. The small showy pink, or sometimes nearly white, flowers, are borne thickly around the upper portions of the branches, and are occasionally crowded so near the extremities as to form almost globular clusters. They appear at the same season as those of the Ling.

Erica tetralix, or the Four-leaved Heath, with some protection, is fairly hardy, and well worth cultivating. The foliage has a dusty grayish hue, and the whole effect of the plant is not so pleasing as either of the other species. Its red flowers,

to thrive well. The very showy, dense terminal racemes of reddish purple flowers are produced during the summer and autumn, but most freely in the latter part of July and in early August. There are forms with darker or lighter or with white blossoms.

Erica carnea has been several times mentioned in these pages for its early spring-flowering habit. It well repays a little winter protection in the fresh pale red flowers which begin to open in the late autumn and may be gathered bright and

unfaded from beneath the snows. Usually only a small proportion of the buds, which are now (August 12th) well formed, open before the spring.

Dabæcia polifolia, or St. Dabæc's Heath, as it is called in Ireland, where it is native, is one of the prettiest and largest flowered of the Heaths which can be grown in the climate of New England. The barrel-shaped blossoms vary from a third to about half an inch in length. The color of the typical flowers is dark purple, but there is also a pure white form in cultivation. The plants are low-growing, spreading and compact; and the flowers are produced in loose racemes on long stems above the mass of shining evergreen foliage. This is a pretty little species for planting in rockeries. But it grows well in any suitable soil, and produces flowers for a long period of time, although most profusely in late summer, when flowers on woody plants are uncommon.

Arnold Arboretum.

Devices for the Fruit Garden.

AT this moment I have four fine Mazzard Cherry-trees covered with mosquito netting to keep off the birds. When only a few Cherry-trees are grown, as is now the case in central New York, robins, cedar birds and cat birds will take every cherry within five days of their coloring. But this fruit is not only very delicious to me, but invaluable as a health preservative. In my judgment the sour Cherries when fully ripe are the most wholesome of all fruits. Generally I cover not only Mazzards, but Early Richmonds and Late Montgomery. Of course the cost of covering will be more than the value of the fruit as a market product; but the same cover will last for two years. Thus protected one can gather delicious Cherries from July 5th down to the end of September. The fruit does not decay badly before September, but ripens and then gets ripier and ripier till the fruit is good enough for Asgard. This device is valuable when one cannot induce his neighbors to plant Cherry-trees by the thousand and so have enough for birds and planters. When we grew a few Raspberries it was just the same; the birds took the bulk of the crop; but now the cat birds and robins are welcome to help themselves and pay for the privilege with music. We do not miss what is taken because we harvest a hundred bushels and are glad to pay a percentage to an orchestra. The Cherry-tree ought to be planted again in this state as freely as it was fifty years ago. The Black Knot has entirely left off troubling them here and therefore even the lazy can grow them.

My remedy for Currant-worms is to plant Gooseberries about the Currant-gardens, and on these the worms first appear. If thoroughly dusted then the attack is far less severe on the Currants. They prefer the gooseberry just as they prefer the white currant to the red. Of course, such preferences are not discoverable when very little care is taken of the bushes and worms multiply beyond all measure. The currant ranks next to the cherry as a matter of wholesome diet. It is to be preferred far above all other berries.

I have Quinces again bearing like the old-fashioned Quince-bushes of my father's day. Thirty years ago I found it difficult to get crops, and till now have only had an occasional peck of quinces. Two years ago I drew the limbs together in November with stout twine, then wound on straw or hay. The result has been heavy crops of fruit. The Quince needs only slight protection here. It is best to plant on a south or south-east slope, and have an evergreen hedge or tight board fence to the north.

I had great trouble with my berry gardens, owing to the hopping down and tangling of the bushes. To remedy this I set stakes about twenty feet apart in the row, and fasten to these one wire, about four feet high. To this wire I tie the new canes in September with strong twine, two to four in a bunch. Then I leave the canes standing six feet high to bear. They are never broken down in winter, and never in the way in summer. The cost is a trifle.

E. P. Powell.

Two Uncommon Plants.

I HAVE lately had two plants in flower which I have never seen elsewhere, and think worthy of more extended cultivation. They both belong to the fibrous-rooted section of the Iris family.

Sisyrinchium striatum, like most of the genus, is native to the lower slopes of the Andean chain, and is the finest of all species known to me, from a gardening point of view. The foliage grows to the height of thirty inches, is flat and flag-like, as in most of the family, having a width of nearly two inches. It grows in dense tufts and is of a beautiful gray-green color, so that if it never bloomed it would still be highly

ornamental. The flower-stalks are often more than three feet high, and are densely clothed for many weeks with closely clustered flowers, three-fourths of an inch in diameter, light yellow, marked with fine lines of a darker shade. Each flower lasts but a day, but new ones are constantly expanding. My plant began to blossom in April, and was in full bloom until the middle of July, and even now, August 11th, there are some flowers to be seen.

This species may be propagated by division, by cuttings of the flower-stem, and, best of all, by seeds, which are abundantly produced. The plant, whose dimensions I have given, is in an eight-inch pot; it is likely that it would grow to a larger size if planted out.

Orthrosanthus multiflorus is an Australian species. Its manner of growth is much like that of the plant just described, but it is not so tall, its foliage is dark green, instead of glaucous, and much narrower. The flowers, also, are less numerous, though they continue to appear for nearly the same length of time. They are nearly an inch in diameter, and are of a beautiful porcelain blue. There is no difficulty in growing this beautiful plant, nor is it at all shy in flowering; every year when April comes round the spikes push up plentifully. Both of these plants derive much benefit from being plunged in the ground during the autumn, care being taken to take them in-doors before frost.

Hardy Flowers for Florists' Use.

IT needs no argument to show that hardy perennials should not be neglected where a mixed collection of plants is grown for sale; but it does not seem so generally understood that many of them are valuable for cut flowers and well deserve the attention of the commercial florist, especially since these plants are well able to take care of themselves, and especially in the winter, when all other things tax all the resources of the cultivator. What can exceed for simple elegance a vase filled with Painted Daisies? And yet how seldom are these single Pyrethrums grown by the florist. They are easily raised from seed and flower the first year. The beautiful perennial Candytufts, too, are much better than the annual kinds. *Iberis correaefolia* and *I. sempervirens* are invaluable where pure white flowers are desired about Decoration Day. The double *Achillea serrata*, a somewhat new plant, will speedily supersede the old *A. ptarmica*, to which it is as superior as the Japan Anemone is to the common Wood Anemone. And certainly no one who grows annual Sunflowers can reasonably neglect the perennial one, so perfect in form, so free flowering and so durable when cut. It is rather singular that this double Sunflower, which I could never persuade to survive a New Jersey winter, has lived out here for years without attention.

The Coreopsis, especially *C. lanceolata*, is pretty well known, but it is not generally known that there are two plants being distributed under this name. The one is a fair plant, but the other is a far better one. It is to be hoped that by next year this case of mistaken identity may be cleared up. *Gillenia trifoliata* and *G. stipulacea*, two beautiful native plants, are both invaluable for mingling with cut flowers, owing to their pure white color and their graceful position on the stems. Both should be grown, as the one follows the other in the order named, and flowers can be had for over a month. The Gypsophilas, especially *G. paniculata* and *G. Steveni*, are most useful among other cut flowers. No other hardy plants have such an airy appearance and loose sprays scattered among other flowers in a vase will surround the whole as with a delicate mist or halo.

Doronicums are sure to be popular, and the leading nurseries are preparing themselves with large stocks, so that they can be purchased reasonably in fall, and if placed in a cool house where Mignonette or Violets are grown, beautiful yellow flowers three or four inches across may be had in February and March from *D. Caucasicum*, *D. Clusii* and *D. plantagineum excelsum*. The flowers of these plants last long, even when cut. The Larkspurs are always popular. Of the single kinds, *D. formosum* is hard to excel among dark blues and it comes readily and true from seed. The lovely sky-blue *D. Belladonna* would be indispensable if it could be raised otherwise than by division, for unfortunately it does not produce seed, owing, it is said, to its hybrid origin. But perhaps the Larkspurs of the future are the double ones. The best way to have them and to keep them is to get named double kinds, save the seed, and raise your own, weeding out the single ones—about ten per cent. of the whole. Larkspurs thus raised will have a strong constitution suited to the locality in which they are grown.

Few persons who have not seen the fine varieties of *Pæonia* that are now to be had can imagine the wonderful range of color and the fragrance of the flowers. They will grow in any good soil, and should not be disturbed except for division—once in three years. *Daphne Cneorum* is essentially a florists' plant, though not an herbaceous one. It is quite hardy, flowers for six months, and is easily grown in free sandy soil. One of the questions to come before the Florists' Convention this week is, "Can Hellebores be Grown to Advantage by the Commercial Florist?" If I might be permitted to express an opinion in advance, it would be emphatically in the affirmative. Had I a commercial place, with a shady border at the back of a greenhouse, I would not hesitate to plant largely the varieties (not the type) of *Helleborus niger*, of which there are now nearly a dozen, all in some degree an improvement upon the older plant. When cold weather comes frames and sashes could be placed over the plants, and the flowers thus protected would yield profitable and speedy returns. The trouble is that Hellebores are usually imported in fall, when they really ought not to be planted until spring.

Omitting other flowers, I may say in conclusion that florists who have ever grown the Eulalias for their fine flower-spikes always find that they meet with universal favor when cut and dried for winter decoration. They will last for years, but are best renewed annually.

South Lancaster, Mass.

E. O. Orpet.

Alocasias.

THIS interesting group of stove Arads includes a considerable number of distinct species and varieties, some of the latter of garden origin being among the finest warm-house foliage plants, while several of the original types are equally desirable. There is much diversity in the form and marking of the leaves of the various sorts, so that most of them are readily recognized.

They are natives of the East Indies and various portions of the Malay Archipelago, though probably not at any considerable altitude, and therefore enjoy warm-house treatment and plenty of moisture during the period of growth, and these conditions will be found essential to their well-being. At the same time it should be remembered that during the winter most of the Alocasias make but little growth, and therefore require but little water; in fact, some of them grow better after a season of entire rest, *A. Fenningsii* and *A. Marshallii* being among this class.

In regard to soil, the Alocasias prefer a light, open compost, as their thick, fleshy roots will not make much headway in a heavy or sodden soil, and for varieties such as *A. metallica*, *A. Sedeni*, *A. Veitchii*, *A. Sanderiana* and *A. Thibautiana*, and others of like characteristics, a mixture composed of rough fibrous peat, with perhaps one-fourth of chopped sphagnum and some sand, will be found most suitable, while *A. macrorrhiza*, *A. zebrina*, *A. Fenningsii* and others of this class make most satisfactory progress when potted in a compost formed of the above ingredients, with the addition of a third part of coarse turfy loam and some dry cow manure, these species being comparatively gross feeders. These plants should in all cases have good drainage, for while they enjoy copious waterings when in full growth, they soon lose vigor when exposed to stagnant moisture. In bright weather they may be syringed freely, especially underneath the leaves, to keep away the red spider; otherwise the Alocasias are but little subject to the attacks of insects.

Prominent among the older varieties may be mentioned *A. metallica* (which is also recognized under the name of *A. cuprea*), a handsome kind, with large bronzy green leaves, which are purplish on the under side and strongly outlined by the prominent veins. This species was introduced from Borneo some thirty years ago, and will still bear comparison with some more recent introductions. *A. Sedeni* is somewhat similar in form and ground color to the preceding, but is improved by the addition of ivory white veins. This variety is one of the finest for exhibition purposes, producing very large foliage and also being of rapid growth.

A. Sedeni was the result of a cross between *A. Lowii* and *A. metallica*, and has been in cultivation for a number of years. *A. Veitchii* is another effective species when well grown, its leaves being of rather different form from those above mentioned, and standing up well on long foot-stalks. They are deep green on the upper side, with whitish veins, and of a peculiar slaty hue on the reverse side. This is also a native of Borneo, and has been long in cultivation. But probably the most striking in appearance of the whole genus is *A. macrorrhiza variegata*, which forms immense leaves of bright green, more or less marked with pure white variegation. The

variegation is somewhat irregular, frequently appearing in large patches, while on other leaves it will be so mixed with the green as to give a marbled effect. *A. macrorrhiza variegata* is one of the strongest growers in the family, and enjoys plenty of heat and an occasional watering with liquid manure. It is said to have originated under cultivation in the island of Ceylon, and may certainly be considered one of the many botanical prizes received from that favored home of tropical vegetation.

Among the smaller growing sorts may be mentioned *A. Fenningsii*, which has leaves about a foot in length, bright green in color, with the spaces between the chief veins occupied by large blotches of dark chocolate color, sometimes almost black. This species is of quick growth, and produces a large number of offsets from its bulbs, which render it of very easy propagation. Of similar character is *A. Marshallii*, though possibly more ornamental, its foliage having in addition to the dark markings of *A. Fenningsii* a central band of grayish white. These two species are natives of India, and have been known in our gardens for more than twenty years.

Another fine species, and one that is not very common in American collections, is *A. zebrina*, which produces almost erect, sagittate leaves of dark green, these being supported by strong foot-stalks that are light green in color and banded zebra fashion with a much darker shade.

The later additions to the Alocasia family have also been numerous and valuable, many of them being hybrids of great beauty, while a number of remarkably fine species have also been introduced.

One of the newer sorts that should not be overlooked is *A. Sanderiana*, a remarkably fine species with sagittate leaves, the margins of which are deeply sinuated and marked with white, as are also the ribs.

Other fine species are *A. Chantrieri*, a hybrid from *A. metallica* and *A. Sanderiana*; *A. Thibautiana*, a species from Borneo; *A. Lucianii*, the result of a cross between *A. Thibautiana* and *A. Putzeysi*, and *A. Lindenii*.

W. H. Taplin.

Hardy Annuals.

ANY ONE who cultivates a collection of plants during a few leisure hours, and has a fondness for experimental gardening, is sure to find days when everything grows the wrong way or not at all, and when failures seem to make up the entire history of the garden. At such times one turns for comfort to the sturdy old plants, perennial or annual, which are always reliable, and require so little attention that, like healthy children, they are apt to pursue their course with little notice. There are numerous hardy annuals which are readily established in the garden, where they will annually reproduce themselves from self-sown seed if the ground is not upset every spring. One learns to expect the annual appearance of these favorites and to welcome them as old friends. Seeds of these plants should be sown from late summer to early winter, and as a rule they should not be covered deeply.

Among the plants which I annually expect are *Argemone grandiflora* (the Prickly Poppy), a good old plant, with beautiful thin white flowers, each holding a cluster of yellow anthers. The foliage is smooth, glaucous and spiny. The branches are irregular and angular in their growth, giving the plant a most distinct appearance.

Chrysanthemum Myconis, which was had from B. K. Bliss some years since, seems a variety of *C. Segetum*, but of better habit and with similar flowers. It adds a gleam of color here and there to the border.

Gypsophila muralis, the dainty little Baby's Breath, is a free seeder, and preserves its race on the edge of a border, but is easily crowded out. It is invaluable for mixing with cut flowers.

Calliopsis tinctoria is one of the best known of annuals, but it is not seen at its best except where full-grown plants have had ample room, when they will cover a diameter of three to four feet, and reach a height as great. Writers who are continually advising us to "give every plant room to reach its full development," do not seem fully aware of the possibilities of well-grown annuals.

Poppies, of course, once grown in a garden may be found in every corner, for their seed crop is enormous and very tenacious of vitality. But for persistent reproduction commend me to the Morning Glory, which it seems almost impossible to eradicate once it has well bloomed in the garden. The seeds will apparently lie dormant for years, ready to germinate quickly under proper conditions. Of course, with care, one could weed out every plant, and at length exterminate it; but one may pursue this course ever so diligently until some fatal day when a plant which has been hiding in some out-of-the-way

corner is suddenly caught in the act of blooming. Human weakness hesitates to destroy so sturdy and beautiful a flower, and the mischief is done for another long course. On the whole, with all their beauty, I am content to admire these with *Petunias* in my neighbor's garden. *Humulus Japonicus* completes a worthy trio of persistent seeders, and is perhaps the worst of the lot. The seeds are light and are blown all over the garden. They germinate with the first warmth of the year. They run and twine in the most aggravating way, making them difficult to eradicate. They would be capital plants for covering large bare places.

Adlumia cirrhosa (Allegheny Vine) is a much neater and more pleasing vine for a small garden, though the withering flowers give it a rather unthrifty look for a prominent place. Though a biennial, it seems never to desert the garden. *Calendulas* may usually be found in the spring, as also a few *Asters*, ordinarily single, and in a dry spot, after a favorable season, *Nasturtiums* even may be found in plenty, and there is a world of pleasure in a good breadth of this beautiful flower.

Union County, N. J.

G.

The Forest.

Suggestions for Restoring Wasted Forests.

ARGUMENT is no longer needed to show the necessity of a more definite policy for the maintenance of our woodlands. Aside from a closer and more economical use of raw material, there is but little difference between present forest-management and that of a century ago. There is the same cutting of everything that it will pay to handle, and the same abandoning of everything else—land and all—to take care of itself as best it may. That some lands become reforested in time, and hence productive, is due rather to kind Nature and good luck than to any intelligent labor or protection. For the most part forest-lands are practically abandoned, and the work of reforestation is indefinitely delayed. Time was when much woodland was cleared for cultivation, but now, with sharp competition under new economic conditions, such areas in the older states grow fewer and fewer, and it has become evident that all lands not profitable for agriculture should be utilized for forest-purposes.

The artificial planting of forests, much as we may desire to see it undertaken, seems yet a long way from us in the eastern states, save possibly on a small scale, or to serve some incidental purpose. The conditions which will make it either feasible or profitable are not visible on our horizon. We cannot create at once that public sentiment which will make effective those laws against trespass and firing, without which the labor would be in vain. We can scarcely hope to enlist the intelligent and painstaking care necessary to secure the best results, nor that faith which is willing to incur so heavy a present expenditure for the sake of remote gain. Time may overcome all these difficulties, and a future generation may adopt a scheme of forest-management as elaborate as that which any part of the world affords. But for our country to-day what can the advocates of forestry-reform offer and recommend?

The answers to this question will doubtless differ for different parts of the United States. Speaking for the eastern states only, and more particularly for Pennsylvania, it is plain to me that very considerable areas are unfit for profitable cultivation or even for grazing, and that their most natural and profitable use is as forests. How can these forests be maintained? In the majority of cases there is a natural reforestation going on through the seeding or sprouting of old trees. While this seems for a time to be ineffective, and the young growth is smothered by weeds and bushes, it commonly gains the mastery in a few years, and, if it meets with no further check, occupies the ground and makes the well known "second growth." In some parts of the country this second growth has become a small but valuable factor in maintaining forest-conditions. In all it is capable of becoming a larger and much more important one. Indeed, in it we have the hope for the forestry of the near future, and toward its production and conservation we should bend our energies. That the second growth is not of the same kinds of trees nor so valuable as the first, are statements only partly true and subject to much exception. Acting upon Nature's method of forest-restoration, that process may be supplemented, and even replaced in some cases by artificial seeding. Some experimental work of this kind looks promising now, but it is too early to speak definitely of either the cost or result of it. It may be argued that, excepting the expense incurred, the same difficulties inhere in this

method of reforestation as in any other. This is true, and it remains to be seen to what extent these difficulties may be obviated. The damage to young woodlands by fire is certainly very great, and is commonly underestimated; the damage from trespass in various forms is no inconsiderable item. Laws, often very stringent ones, have been enacted for the protection of woodlands, but they are practically of no avail in so far as fire is concerned, since punishment under them is of rare occurrence. In the eyes of people generally forest-property has an insignificant value unless it has reached maturity and can be immediately turned into money. If it is isolated or too young to be of immediate use it is looked upon as of little account. Unfortunately the owners themselves are generally too indifferent to give sufficient care to their property. Either because of lack of knowledge and of faith in the productive value of such lands, they make little effort for self-protection, and through their indifference and the lack of suitable policing, the natural forest-lands are too often sparsely covered, the trees grow old before their time, and are useful only as a commentary on our shortsightedness. The danger and the damage to the community from this unfortunate state of affairs are well known, and it remains to inquire if anything can be done to remedy this unhappy condition.

Two plans occur to me as worthy of trial, one by the owner and the other by the community.

When it is desired to protect the fish in a stream or the fruit in an orchard the owner posts a conspicuous notice to forbid trespassing. Let him do the same on his forest-property. Some kinds of trespass, such as the pasturing of cattle in open and mountain woodlands, can be easily controlled; some, such as hunting, berry-picking and the like, not so easily; but the moral effect will be the same in all, and it will make prominent the fact that the owner has some care for and interest in his own. Such notices if prepared in large quantity could be made cheap and durable, and placed where they would command attention. Can our forestry associations, agricultural and other organizations render any more effective service for the cause than to agitate this matter, and urge our farmers and land owners to undertake it; or even to prepare and furnish such notices at a nominal price to all who will agree to use them? Much that is technically trespassing is not injurious, but this distinction could be safely left to the owner, as are many other matters. What is needed is a public sentiment which shall look upon forest-property, in any state and condition, as in no respect different from any other kind of property, and which shall secure for it the same immunity from injury. If nothing is done such a sentiment may come at last, but it will come very slowly. By some such means as has been suggested may we not hasten it?

Undoubtedly the prevention of forest-fires is of prime importance, and our chief effort should be toward that end; but when fires are kindled, as they will be under the most careful supervision, how can we control and suppress them?

The same apathetic condition of both the owner and the community is to be faced here as in the case of trespass. The fire is left to burn until it has passed beyond control, and it stops only when everything inflammable within its reach has been consumed. Disgraceful examples of the truth of these statements are so common that they form a staple part of our daily news. To have an adequate sense of the injury done by these conflagrations one must have a knowledge of the indirect as well as the direct value of forests, and must bear in mind also the relatively long time required to produce a forest-growth. Were proper attention given to the matter we should be so keenly alive to the value of forests that fire or any other agency which threatened to destroy them would be as quickly and vigorously combated as if some monumental building were exposed to destruction.

Forest-guards are charged with this duty of protection in other countries and we have no officers corresponding to them. But why may we not add to the duties of some existing township officers, say the supervisors or constables, the oversight and control of all fires, accidental or other, on farming and forest-land? There would then be some responsible head for each district, who would have power to summon help, to give or refuse permits for burning clearings and the like, and who should receive reasonable compensation for these special duties. An innovation like this, although so small and at the same time so well warranted, might still meet objection, it is true, but the same difficulty would probably appear if any other plan were devised.

The forestry question, from every point of view, is subject to the same economic laws as any other, and its advocates should be able to point out practicable methods for its solution.

The same conditions which are slowly but surely changing our methods of agriculture are opening the way to and making possible a rational forest-practice. We cannot too quickly or thoroughly consider what shall be its methods.

Correspondence.

The Effect of Seasons on Vegetation.

To the Editor of GARDEN AND FOREST:

Sir.—Too much care cannot be taken in judging of the character of trees, shrubs or fruits by their behavior during 1890. The season is so far abnormal in every sense. Strawberries, for instance, have not developed one of their real characteristics in my beds, Crystal City, Summit and Sharpless alone excepted. Haverland, which really is a very large berry, showed fruit only medium-sized and without flavor. Sweet berries turned up sour, and nearly everything had a touch of bitterness. In fact, symptoms of unfertilized fruit were general. I should not have known Bubach in boxes; and Bomba turned out better than its real character. I have seen no really perfect strawberries in size, flavor and color, although I had one-third of a crop and many large berries. But had I desired to impart to any one knowledge of the real quality of any berry I should not have done it by offering him samples of this year's bearing. For this reason I regret to see reports of berries made at all this year. My Pearls and Sharpless and Bubachs when mixed I could not have separated with certainty, although another year nothing would be easier.

The effect of season is very peculiar in other ways. One summer ten or twelve years ago there was an unusual tendency to produce variegations in foliage. This, no doubt, had something to do with the effect of the solar beams on chlorophyll in spring. I regret that I have no meteorological data of the year. But I noted among my own finds a variegated Quince-bush, variegated Silver Poplar, variegated Apple, and many more. None of them endured July heat except the Poplar. This I unfortunately lost by the open winter following. It was heaved out by the frost.

I am confident that we have before us a vast field for investigation in a comparative study of different years on foliage, fruit and flowers. In 1889 I noted here a marked tendency among double flowers to show fewer petals than usual. To determine the real character of a fruit or flower requires a comparative test. Grapes particularly appear very abnormal at times. If any one were to pass through my vineyard on two successive seasons I am quite confident I could get from him exactly opposite comments concerning Grapes, especially Rogers' Hybrids. Here is a class of Grapes sensitive beyond measure to the year's special characteristics. Number 30 is at times equal to a fine hot-house variety; then again it is flavorless. Lindley one year cannot be surpassed, while the next it is inferior. To discard the variable sorts would reduce our list very greatly. Even Worden in 1889 was of poor quality over a large part of the country.

E. P. Powell.

Shaftesbury as a Tree-Planter.

To the Editor of GARDEN AND FOREST:

Sir.—In Traill's Life of Shaftesbury, published by Appleton in 1886, on page 104, is the following interesting passage on tree-planting: "In the very thick of the tangle of intrigues, rivalries and cross-purposes in which the cabal were involved during the year which elapsed between the conclusion of the second Treaty of Dover and the reassembling of Parliament in 1672, we find him [Shaftesbury] addressing a long letter to his bailiff, containing the most minute instructions for the planting of several varieties of the best cider Apples, to wit, 'the Red-streak, the Black Apple, the Streak Must, the Sour Pippin, the Bramsbury Crab, the Grouting.' Further he goes on to inform 'Hughes' (who, no doubt, was intimately convinced of his knowing much more about it himself than the authority quoted by my lord) that the best planting of timber-trees is 'with nuts, acorns, seeds and footsets, and not with young trees removed; and in that manner of planting where the ground is dry, he never plants on little hills, banks or ridges, but sows and sets them on the plain ground, having first made it with several plowings and diggings very light and fine, which should be begun about September, that the frost might season the earth against the spring, when you plant. When this is done the roopworm is killed and will not annoy the plants. He useth constantly' (does this experienced gentleman by whose

woodcraft Hughes is being put to shame), 'in setting of chesnuts, acorns and seeds, to steep them twenty-four hours in milk, which gives them a great advantage; he sets his seeds and plants five feet one from another, and sets the two first years among them beans, which not only pays his charge, but, as he affirms, extremely cherisheth the plants. He waters his plantation the two first years only. . . . He plants an abundance of the best sort of Filberts among his plantations of timber. I would have you do the same amongst mine. He assures me that if I plant Siccamos near my gardens they will spoil all my fruit with the flies they breed. Therefore pray pluck up all the Siccamos that are in the dry meadow behind my kitchen garden, and in the room of every one of them plant a Chesnut, a Walnut or a Honey-broke Oak.'" J. N. B.

Brooklyn.

Tecoma grandiflora.

To the Editor of GARDEN AND FOREST:

Sir.—I am glad that you called attention to the merits of *Tecoma grandiflora* in last week's paper. Perhaps the reason that this fine old plant has not been more generally used is found in the fact that it is sometimes rather tender when young, but if it can be protected until the main stem is some years old by straw matting during the winter it will be found perfectly hardy, and no plant at this season can show an equally beautiful bloom. A plant by my house is probably thirty years old, and its main stem is as large as a man's arm. I have just counted twelve open flowers on one of the immense panicles, with twelve buds yet to open. Since these flowers are borne on the wood of the year hard cutting back will increase the abundance of its bloom. When tied to a stake for a time its stem will become self-supporting to a height of four or five feet, and from early August until hard frost the plant will make a conspicuous and elegant appearance. I think that some large-flowered forms of *T. radicans* have been occasionally called *T. grandiflora*, but the distinction between the plants will be evident to any one who examines them.

Flushing, L. I.

S. B. Parsons.

Sargentia Greggii.

To the Editor of GARDEN AND FOREST:

Sir.—Since writing of this plant (page 362) I have found it in mountain cañons about the Pass of San José (Villar Station, on the Tampico branch of the Mexican Central Railroad), attaining the average size of trees, fully fifteen inches in diameter. Here at last it was seen in full bloom, its bright green foliage half hidden by close panicles of white flowers three to six inches high, a beautiful tree indeed.

Associated with it in these mountains was found, as I was convinced, another species of this new genus, a large shrub, with leaves mostly simple, pubescent and olive-green in color (those of *Sargentia Greggii* being trifoliate and smooth), and small clusters of flowers scarcely paniculate.

San Luis Potosí, Mexico.

C. G. Pringle.

Recent Publications.

A Manual of Orchidaceous Plants.—Part VI. *Cælogyne*, *Epidendrum*, etc. Messrs. James Veitch & Sons, Chelsea.

The sixth part of this useful work, which has recently appeared, is devoted to the genera *Cælogyne*, *Epidendrum*, *Spathoglottis*, *Phajus*, *Thunia*, *Chysis*, *Calanthe* and a few others, or such of the species as are usually found in cultivation. It extends over 134 pages and contains about forty excellent wood-cuts. It is treated in the same excellent and comprehensive manner as in previous issues—details of the history, introduction and cultural requirements of the different species being given, also their geographical distribution, synonymy and references to original descriptions and figures, all of which enhance the value of the work.

In those genera from which hybrids have been raised we find an enumeration and description of the several kinds given after that of the species. The notes and illustrations under this head are particularly interesting, and include the genera *Calanthe*, *Chysis*, *Epidendrum*, *Phajus* and *Thunia*, also the curious bigener raised between *Phajus* and *Calanthe*, to which the name *Phaio-Calanthe* × has been given. In the case of *Calanthe* these hybrids are becoming rather numerous, and seem likely to become more so, for the facility with which they can be produced, and their comparative precocity in flowering, as well as their beauty, all contribute to the interest attending the raising of them.

Of the work generally it is enough to say that it fully maintains its high standard of excellence, and from the long experience which the authors have had in the management of this interesting family, there can be little doubt it will prove invaluable to cultivators generally. The succeeding part is to include *Phalenopsis*, *Ærides*, *Vanda* and the allied genera, according to announcement, and will doubtless prove exceptionally interesting.

Notes.

A monument is to be erected in Salisbury Cathedral to the memory of Richard Jefferies.

A statue of Linnaeus is to be given to the City of Chicago by its Swedish residents, and will be placed in Lincoln Park.

"Ten-thousand-times-sprinkled-with-gold" is one of the poetic names which the Japanese are fond of bestowing upon their *Chrysanthemums*.

A catalogue of his collection of Orchids, recently distributed by Mr. Van Imschoot, an amateur of Mont St. Amand, Belgium, with the view to facilitating exchanges between himself and other amateurs, contains the names of about 800 species and varieties.

The Superintendent of the Public Gardens at Launceston, Tasmania, writing to *The Garden*, says: "All our *Chrysanthemums* are grown out-of-doors in the open garden; the climate here suits them admirably. . . . Mrs. Alpheus Hardy has just flowered here and is attracting a good deal of attention."

Foreign journals note with approval that the Prefect of Savoye has forbidden the gathering of *Cyclamen Europæum* in the woods of his province, the beautiful plant being threatened with extermination by collectors who annually send it in enormous quantities to the markets of Chambéry and Aix-les-Bains.

At Gooseberry shows in Warwickshire prizes are given for single berries, and the first premium this year in Faleshill, near Coventry, was taken with a red berry weighing an ounce and a quarter, and looking, as *The Fruit Trade Journal* reports, more like a plum than a gooseberry. No exhibits were admitted to this class which did not weigh an ounce or more.

At the recent great horticultural exhibition in Berlin, visitors were asked to record their opinions as to which was the most beautiful *Rhododendron* shown. The favorite proved to be the rosy lilac *Everestianum*, so deservedly popular in this country, for which 12,800 votes were cast, while a variety called *Limbatum*, having white flowers with a crimson edge, came next, and *Viola* third on the list.

An example of the way in which plants seek for nourishment in sterile situations was noticed recently by a correspondent of an English journal, writing from Florida, who says that under groves of dwarf Oaks, where the soil is too poor to bear grass, *Cacti* (*Opuntias*) may be found which, although not rising more than six inches above the ground, have roots that extend eight or ten feet horizontally just beneath its surface.

The highest mountain in the Hartz range, the Brocken, so intimately connected with legends of the Devil and his cohorts, is to be brought into line with the world's general tendency toward scientific rather than superstitious thought. A botanic garden is to be established there, under the control of the Director of the Botanical Garden at Göttingen, for the purpose of cultivating the plants indigenous to the mountain itself and to other lofty places in the neighborhood.

A correspondent of the *American Florist* says that while in 1874 there were but thirty-three florists in San Francisco there are now seventy-two, and that "all over the state the same proportionate development is manifest. The improvement in public taste," he adds, "during the past five years is still more clearly marked; quality is more desired and better prices are paid. The Daffodil, for instance, then very rare, has become the prime favorite for a spring flower, and the California wild flowers, which no florist kept for sale five years ago, now fill large windows on the principal streets."

Many writers in foreign journals are just now calling attention to the great value of the Locust (*Robinia Pseudacacia*) for planting in situations where it is desired to prevent the shifting of loose soil. One example cited is of very large plantations recently made in Roumania along the borders of the Danube upon banks of sand. "Thanks to the excellent character of the tree," says the *Revue Horticole*, "which will grow almost anywhere, these plantations have succeeded very well, and

they have the double advantage of solidifying the shifting dunes and of furnishing an excellent wood, while utilizing surfaces which hitherto had been wholly unproductive."

In an address before the Columbus, Ohio, Horticultural Society, Professor W. J. Green said that it was now easier to grow Plums and Pears than formerly, and of late these fruits have been among the most profitable fruit crops. In planting, a heavy, tenacious, wet soil should especially be avoided. No manure should be applied to Pear-trees. They will not stand forcing, as blight sets in when they grow too rapidly. A steady, slow growth is safest. Only a few varieties should be planted as dwarfs, and in general it is better to plant standards. The only safe dwarfs are Clapp's Favorite and Duchess d'Angouleme. These are also good as standards.

At a recent meeting of the California Academy of Sciences, Doctor Gustav Eisen spoke of the Sequoia forests in Tulare County, which have lately been surrendered to lumbermen by the Land Department. Doctor Eisen says that the destruction has begun in earnest already. On the Tule River he examined the stump of one tree which was forty-one and a half feet in diameter. These trees are so conspicuous as individuals that each one has a name of its own. The one mentioned above was called "Philadelphia," another is called the Centennial, and a third, known as the "California Stump," is thirty-three feet in diameter, and 60,000 shakes were made from the tree. After Doctor Eisen had explained the shamefully wasteful methods of lumbering in these forests a committee was appointed to memorialize Congress for the protection of the only remaining grove of these giant trees.

Mr. Horsford's mention of *Sabbatia chloroides* recalls the fact that great masses of this beautiful wild flower often form a conspicuous feature of the August exhibitions of the Massachusetts Horticultural Society, and it is sometimes offered for sale by the florists of Boston. At the summer resorts along the New Jersey coast great quantities are brought in by boys from the moist, sandy barrens, where it grows in great abundance, and a ready market is found for it. A mass of these delicate pink flowers loosely set in a vase is very ornamental. The flowers remain in good condition long after being cut and the unexpanded flower buds continue to open for many days. The delightful fragrance of the *Sabbatia* gives it an additional charm, and it is no wonder that large and increasing orders for the seed of this plant are coming over from Europe every year.

The Crescent has hitherto been considered the best market Strawberry in central Ohio, but the comparatively new varieties, Bubach, Haverland and Warfield, are all so good that it is difficult to determine which of the four deserves the precedence. At the Ohio Experiment Station they easily excel all other varieties in productiveness, and they all have imperfect or pistillate flowers. "And why should we not expect this?" asks Dr. Lazenby, in *The Country Gentleman*. "The production of pollen is an exhaustive process. If the vital energies of the plant are expended in this way, certainly we cannot expect as good a result in developed fruit as we can where no pollen is produced. We must remember, however, that in order to get the best results, these imperfect varieties must be well fertilized. Whether it is better to use a productive perfect variety as a fertilizer, or to use one known to produce a large quantity of pollen, and that at the right time, without reference to its fruit, is an open question."

We have received by mail from Mr. P. J. Berckmans, of Augusta, Georgia, a flowering branch of *Leucophyllum Texanum* a shrub which has rarely if ever been seen here in cultivation. Mr. Berckmans writes that he tried for years to propagate this species with living plants, cuttings and seeds; but he never succeeded until some five years ago, when two plants were started. These are now four feet high, and with their ashy white foliage and abundant purple flowers, they are very conspicuous. They endure the warmest and driest weather well, since their large roots penetrate the soil to a great depth. The foliage, which is evergreen in its native habitat, stands without injury a temperature which does not fall below fifteen degrees Fahrenheit, and these plants have lived through a freeze of five degrees above zero. In writing of the forest-vegetation of the Lower Rio Grande Valley, Mr. C. G. Pringle speaks of this plant (see vol. ii., p. 394) as the most striking shrub of the region, and calls it "surpassingly lovely, with a profusion of purplish bloom surmounting the velvety white foliage." No doubt it will prove a great addition to our list of shrubs for latitudes south of Washington, and it may survive winters much farther north if slight protection is given to it.

Growth in Thought Relating to Forestry Matters.

THE principal gain in relation to matters connected with forestry and the preservation of scenery in this country in the last two or three years is probably the increasing definiteness of thought regarding them. More persons comprehend the truth that if anything is to be accomplished in the way of improvement in the condition of these interests much work will be required, and some money must be expended. There are new organizations and activities for the promotion of such objects in this state, in Massachusetts, New Hampshire and Maine, and their influence, in conjunction with the increasing discussion of these subjects by the press of the country, has led to a perceptible advance in public thought. There is increased clearness, definiteness and sobriety, and less hazy enthusiasm and fantastic talk. The new temper is more favorable to action than the old, although there is still room for much improvement in all these respects.

Meetings, addresses and essays have their place and are often highly useful, though more is usually expected from them than they are really suited to accomplish. They are good only if they lead to something beyond themselves, to intelligent and systematic endeavor to change the condition of the public mind and the course of public action in relation to the particular matter which requires improvement. Unless orderly and persistent work of this kind is contemplated, and is actually provided for and taken up in action adapted to bring in a new order of things, it would often be better not to start a new movement or publish resolutions setting forth the plan of a great reform. An abortive beginning of this kind makes all subsequent effort for similar objects more difficult, and the effect is depressing and injurious in proportion to the attention and expectation which have been awakened.

Enthusiasm is a good thing in such matters if it is of the enduring kind which sustains a man in a long course of effort to arouse public interest and enlighten and direct public sentiment. In every attempt to bring about an

advance in matters pertaining to forestry interests in this country, or to scenery and public out-of-door possessions and opportunities, the greater part of the work, and much the most difficult part, is that of interesting and engaging the people in support of the proposed measures of improvement. The question of means and methods for the diffusion of knowledge and the propagation of ideas is what chiefly requires attention. The difficulty of work of this kind, and the amount of it which will be necessary, are nearly always underrated by those who plan new movements. In many instances this part of the work seems to be left out of sight altogether, and its necessity is not recognized. Apparently, it is expected that the existing order of things will be entirely changed by the adoption of resolutions and the election of a board of officers.

But the best possible beginning avails little unless it is followed by a new course of action. If anything valuable is to be accomplished new centres of energy must be established and new activities must be set up. To bring about any considerable improvement in the situation of the interests connected with the forests or with scenery, in any of the states of this country, much conference and correspondence would be required in order to bring the people who are interested in such objects into relation with each other, and thus render effective co-operation possible. It is important in any effort of the kind not to undertake too much at first. After a definite purpose is outlined which can be commended to the public as moderate, reasonable and desirable, the main idea must be developed, patiently and clearly, and its relations to existing conditions and interests fully set forth. Few persons will attend or heed at first, and prejudices and prepossessions of all kinds have to be overcome. It requires time and much iteration of impressions to change habits of thought and action. There is little chance for the success of such undertakings unless obstacles which are certain to be encountered are recognized at the beginning. Any successful enterprise of the kind must have a business basis, and business methods must be followed so far as to provide for necessary expenditures. But many persons think themselves deeply interested in local movements for the preservation of scenery and in similar objects who never really assist in any effective way. They never reach the stage of serious or definite thinking in regard to the matter. The movements for the preservation of scenery in various states of this country afford opportunities for valuable service to the general welfare which should be most welcome to men of public spirit.

A year ago Mr. William McMillan, Superintendent of Parks in Buffalo, read a paper before the Society of American Florists, in which he argued in favor of the natural treatment of grounds which are large enough to have a distinctive landscape character as opposed to what is known as decorative treatment. That is, beds of bright colored plants were spoken of as altogether out of keeping with a picture of pastoral simplicity. Mr. McMillan pursued his argument with some raillery against staring contrasts and loud colors and the use of trees and plants with constitutional deformities instead of a more moral, quiet and delicate style of art. It was said that if the opportunity had been given to reply to Mr. McMillan his position would have been criticised by many members of the Convention, and, therefore, at one of the sessions of the Association in Boston last week the question was again brought forward with the avowed purpose of continuing the discussion. It would naturally be supposed that members of a calling whose business is primarily with flowers would favor the use of material with which they are most familiar—that is, that they would insist upon the splendors of color which can be furnished by conspicuous flower beds as an essential feature of planting. But, in truth, it seemed that the majority rather preferred the kind of art which Mr. McMillan advocated.

The fact is that the florists of the country have been doing a great deal in the way of introducing more simple and quiet arrangements. Even in cut-flower decorations the stiff and formal designs of a few years ago have been superseded by more natural grouping and more delicate shading in the colors used. Perhaps there is no real conflict between the two schools so-called, and that there is no reason why each one should not appreciate the value of the other. The statement made by Mr. Manning, of Brookline, that we must recognize two distinct arts to which the name of gardening is applied, seemed to be generally accepted. Landscape gardening deals more with the fundamental and permanent features of scenery, while decorative gardening is confined to more contracted spaces where the treatment may be highly ornamental and modified every year. Neither one of these should be adopted to the exclusion of the other, and the real question is, under what conditions landscape gardening proper is to be preferred to decorative gardening, or how far the two can be used together without conflicting so that each one would detract from the value of the other.

It will hardly be disputed that formal beds of flowers can be placed so as to disturb the quiet and unity of a meadow, and that on the other hand a stretch of green sward with its irregular border of shrubs and trees would be an inappropriate setting for a brilliant piece of carpet bedding. The fields for the exercise of good work in both directions are sufficiently numerous. There is abundant room for formal planting in connection with architectural terraces and monumental buildings, and there is no reason why persons who appreciate good work of this sort cannot relish also the broad and park-like treatment of larger public grounds. The discussion was interesting because it proved that every year there is a larger number of people who take correct views of the principles upon which both kinds of gardening should be based.

The Sacred Olive-Tree of Blidah.

A PORTRAIT of the Olive-tree in the Garden of Gethsemane was published in one of the early numbers of GARDEN AND FOREST (i., page 284). Less widely known and less interesting, certainly, to the peoples of western nations, are the sacred Olive-trees of Blidah, one of which appears in our illustration on page 419, although these trees have long been revered by the inhabitants of Algeria, and are familiar to travelers in that country. The sacred grove, of which our tree is one of the largest individuals, was planted, so goes the story, by the hand of a famous Marabout, who prophesied the destruction of this modern Nineveh, in the days when Blidah was known as the "wicked city," from the depravity of the rich Arabs who flocked to it to pass the summer months. The prophecy came true, for an earthquake, which lasted during four days, destroyed in 1825 the lives of 7,000 of the inhabitants of Blidah, but spared the sacred grove and the tomb of the prophet, Mohammed-el-Kebir, which it shades.

Our illustration is from an Algerian photograph placed at our disposal by Mr. Francis Skinner, of Boston.

The Arboretum of Dr. Dieck at Zoeschen.

AT the ancient Saxon city of Merseburg, built by the Emperor Henry the Fowler, one is truly in the heart of central Germany. Immense plains, unfolding themselves toward the distant hills which to west and north border the horizon with a line of blue, a rich alluvial soil traversed by the Saale and its tributaries, a whole province where spontaneous vegetation has, so to say, disappeared beneath an overlay of infinitely careful cultivation—this is the aspect of the country through which we pass on our way toward Zoeschen. Towns and villages solidly built of hewn stone breathe of comfort and give themselves the air of a German Goshen; they swarm with a well dressed population and bear the seal of an ancient civilization.

"Here is Zoeschen," says the driver, and we traverse the village, which is more exactly a little town, pretty and cleanly; and, at the end of a short street, diversified by rural-looking gardens, we enter a verdurous avenue that, making a turn, carries us along a bridge over a brook whose troubled waters

show the effect of this eminently rainy summer. Another turn among great trees, dominated by an enormous Canada Poplar, and the carriage stops before the entrance of a fine modern villa, where Dr. Dieck is standing to offer us the hospitality of his estate.

This oasis of arboriculture, in the midst of the prose of endless fields of grain, is of recent origin. It does not impress us by means of ancient trees or of magnificent perspectives losing themselves in great forests. All these there are, but in the distance. What Dr. Dieck calls the "National German Arboretum" exists as yet only in an embryonic state, although conceived on a grand scale. It has been laid out over an area of six hectares, at a half hour's distance from the house and the park, on low grounds rather too subject to the inundations of the little River Lupa, a tributary of the Saale. The trees and shrubs have been planted recently in groups, at well judged distances from each other and with regard to the natural families to which they belong. Several unfavorable seasons have but too greatly retarded their development and left wide gaps which must be refilled. Everything that the catalogues offered in the way of old acquaintances and of novelties beginning to be somewhat known has been confided to the soil, and it is proposed to add without delay the whole assortment contained in the nurseries of Zoeschen, a truly astonishing quantity. No difficulties daunt the proprietor. After three consecutive years of the most discouraging sort, he has just enriched the Arboretum with 300 new species or forms which are not mentioned in any catalogue, even his own. An old tile-factory, which adjoins the plantations, is about to be renovated, and will serve as a botanical and silvicultural laboratory.

But, after all, the Arboretum is not the greatest glory of the Zoeschen establishment, for, however grandly prepared, it is as yet a work of the future, counting for little at the present moment. While the Arboretum at Muskau, founded with such fair hopes by Petzhold, is sadly dying on its sandy hill, that at Zoeschen is but just emerging from the dampness of its alluvial soil. A future generation will admire it, but what impresses us to-day is the greatness of the idea conceived by its founder.

Present interest centres chiefly in the nurseries, which surpass those of Angers, and already rival those of Herr Spaeth, near Berlin, and which include a vast collection of species, forming an extraordinary collection of novelties, some of which are of almost fabulous rarity. Dr. Dieck has a rare energy and an inborn passion for the works of nature. He travels widely and himself collects plants, seeds and insects; where he cannot go in person he sends his agents, and he perpetually animates the pen and the industry of innumerable correspondents in fulfilling his mission to disseminate the vegetable species of the whole globe and enrich the flora of his fatherland. The word impossible does not exist for him when rare plants are to be won from foreign countries. A mere private citizen, he has established solely for his own use eight stations through central Asia from the Caucasus to the Japanese island of Yezo and into the depths of Siberia, with a branch toward the west embracing Bulgaria, Asia Minor and Mount Lebanon.

His nurseries now cover a space of 100 acres, which will soon be increased to 125 acres, as large an area as can be kept in good order. The great mass of the plantations extend beyond the Arboretum, stretching toward a vast and magnificent forest of Oaks and Lindens, Ashes and Maples, which is called "The Great Wood," and which reaches nearly to Leipsic, along the course of several little rivers. Here are great plantations of forest and avenue trees; there conifers brave a climate which is unfavorable for them, often under the protection of shutters and rushes. It is worthy of remark that the German Fir (*Abies pectinata*), the natural area of which extends as far as Lithuania, freezes here, and that the Douglas Spruce does very poorly, while certain species reputed tender seem, on the contrary, entirely hardy.

The seedling-beds of Zoeschen, which make the most astonishing feature of the place, occupy an immense space back of the park proper. A great enclosure protects them, as is likewise the case with the conifers. Here one finds also the *plantes de la terre de bruyère* of the Rhododendron class, Azaleas, Kalmias, Ilexes and other broad-leaved evergreen shrubs. It is not too much to say that this last class contains marvels, as, for example, among those most recently introduced, *Rhododendron Ungerii*, from the Caucasus, with brilliant foliage silvered beneath; *Phillyrea Vilmoriniana*, from the mountains of Pontus; *Bruckenthalia spiculiflora*, from the Bythinian Olympus; *Quercus alnifolia*, from Cyprus, which might better be called *Q. camelliaefolia*; *Eleutherococcus*, from the Amour

River; *Magnolia hypoleuca* and *M. parviflora*, the Japanese Stuartia, and many more, including innumerable *Vacciniums* and other *Ericaceæ*, which are difficult to cultivate, and which have been chiefly furnished by America.

The number of wild Roses, species or varieties, is simply startling, and of especial importance in this department are the Oil Roses. To Dr. Dieck is due the credit of having wrested the monopoly of their culture from Bulgaria. Here the queen of flowers is brought down to the level of prosaic vegetables, and cultivated not in the privacy of gardens, but side by side with Cabbages and Carrots. This new branch of agriculture seems to have a prosperous future. The product—that is, the odoriferous petals—can be advantageously sold to several large manufactories of perfumes in Leipsic. It is especially Herr Scheele, of Schadebach, near Zoeschen, who has taken in hand this new enterprise, which demands a very fertile soil or one strongly enriched and deeply trenched. He has planted vast fields, which look like vineyards, with the oil-producing Roses of the Balkan, among which *Rosa trigintipetala* seems to promise best, in spite of the attacks of a certain fungus. These Rose plantations are kept with wonderful neatness, and one seeks in vain within them for the tiniest weed. They yield annually a net return of \$300 an acre, surely no mean profit. Dr. Dieck proposes to study thoroughly the Rose of Schiras, which will probably prove to be *R. moschata*, and the attar of which, he says, is the most precious of all, though as yet unknown outside of Persia.

It is surprising to see the way in which certain newly introduced American plants are growing at Zoeschen. In this respect nothing surpasses the development of *Alnus rhombifolia* and *Betula occidentalis*, natives of British Columbia—nine feet in two years and five months from sowing!

The park at Zoeschen, although not old and for the most part planted by Dr. Dieck himself, nevertheless possesses some very fine trees even, as might be expected, among very rare species. The Sophora and the Ailanthus prosper, and the Liquidambar does very well. I also remarked on a lawn near a bit of water a superb group of *Glyptostrobus*, that curious Chinese representative of the American Bald Cypress. These specimens are grafted on *Taxodium*; but this does not detract from their appearance. Furthermore, one admires here a Japanese Walnut (*Juglans Sieboldiana*) of the finest expression, and differing much in its foliage from *J. Mandschurica*. A little known Rhamnus, of the *Frangula* group (*R. sempervirens*), here extends its large masses of foliage, which resist the cold until Christmas. I noted *Cornus alternifolia* in the form of a little tree, which spreads its branches in the most striking way; and here I saw for the first time *Aralia spinosa* and *Panax sessilifolium* in full fruit.

But, caring even more for great trees than for rare ones, what charmed me most was a giant *Robinia Pseudacacia*, that terminates and dominates the large lawn facing the house.

Berlin.

Carl Bolle.

[It would appear that many plants from Japan, which are comparatively rare in European gardens, have been grown for years in America. Taking those named at the head of this column for example: A specimen of *Magnolia hypoleuca*, twenty-five years old, stands within the limit of this city, while *M. parviflora* and the Stuartia have been known for years in our suburban gardens.—Ed.]

Notes on the Mexican Water Lilies.

NATURE, lavish of her gifts in tropical climes, has sown in Mexican waters a larger and more pleasing variety of the flower dedicated to the water nymphs of ancient mythology than is found in our northern lakes. The species, as far as known to me, are four: *Nymphaea Mexicana*, Zucc., with yellow flowers, *N. elegans*, Hook., blue flowered, and *N. ampla*, DC., and *N. gracilis*, Zucc., with white flowers. The range of distribution of all of these, with one exception, extends within the present limits of the United States—*N. ampla*, *N. elegans* and *N. Mexicana* being known to occur in southern Texas, and the latter, if, as is strongly suspected, this species is identical with *N. flava*, in Florida also.

N. Mexicana I have traced from the lagoons of the lower Rio Grande southward to the lakes of the valley of Mexico, and westward to the slow streams of the great valley of the Lerma, in the state of Jalisco. Its leaves are six or seven inches broad on their upper surface, which is dark green and shining, sparingly splashed with purple, exactly in the way of the Florida plant; its flowers, two or three inches broad, are borne on erect stems eight to twelve inches above the leaves lying on the surface of the water, or rising out of the water when

crowded; their sepals and petals are acutish, the former being purple without, but inward blending with yellow, and the petals, as also the stamens, lemon-yellow. Its rhizome is scarcely more than an inch in thickness and only a few inches in length. A striking peculiarity of this species is its multiplication by means of runners, just in the way of the Strawberry. Young plants are thus freely sent out from the rhizomes of plants formed in this way the previous year, and from the young plants themselves very often, being borne on white spongy cords half an inch thick and one or two feet long. These young plants usually flower after a few weeks, while yet attached to the parent plants. Thus the flowering of the species is prolonged from June till October.

Pleasant are memories of fields of this plant, deep green enlivened by abundant yellow blooms, seen by me in valleys lying under serene golden skies and rimmed by blue sierras.

N. elegans I take to be a denizen of the warm lowlands only, ranging from the Waco River, in Texas, southward through the Mexican Gulf state of Tamaulipas to that of Vera Cruz, at least, perhaps much farther. In the shallower lagoons of the lower Rio Grande—former channels of the river, now tortuous lakes, isolated throughout most of the year from the river's flow—it is so abundant as to cover large expanses of water.

In the size of its leaves and in the size and shape of its flowers this species is similar to the preceding, but the flower-stem is perhaps taller and more slender. The outside of the sepals is green, marked with fine broken lines of purple; the petals are of various shades of blue, while the centre of the flower, the stamens and stigma, is pale yellow. Its rhizome is as small as that of *N. Mexicana*, and it is propagated only, I think, by means of seed. Unlike those of the species just mentioned, these are very numerous and very small.

I well remember my delight when first I came upon a lake covered with this plant, whose flowers were opening in the sunshine of the morning and seemed a reflection of the blue vault bending over them.

The habitat of *Nymphaea ampla*, as well as I can judge, is more restricted. Certainly I have only met with it on or near the table-land of northern Mexico in springs here and there or in the limpid streams flowing from them. The striking peculiarity of this species, among those which are native to America, is indicated by its specific name, its leaves being a foot or more in breadth. These are purple beneath, with prominent veins. The Mexican name of such Lily-pads is *lampazos*, and they have given name to a town on the line of the Mexican National in Nuevo Leon, whose *raison d'être* upon desert mesas is a vast spring occupied by this species, and probably to a Texan town also. The flower of this species is scarcely larger than that of the preceding; its petals being white; the rhizome is somewhat thicker and longer.

Nymphaea gracilis I only know in the region drained by the Lerma, yet this is a wide region, extending from Aguas Calientes and San Luis Potosi on the north to near the City of Mexico on the east and south and to beyond Guadalajara on the west. It is the fertile and populous heart of Mexico, the region of frequent large cities and of green garden lands.

As the train of the National Railroad nears the mountain rim of the green valley of Mexico you see this Water Lily whitening the surface of the fountain lake of the Lerma, newborn from the snows of the Volcano of Toluca; and it is to be found in lakes, natural and artificial, and sluggish streams tributary to this great river far and near. Sometimes it yields place in these waters to *N. Mexicana*; but it seems to be the more common species here. The tall and slender flower-stalk rising a foot above the water, and the rather narrow and acute petals, give this plant the slender appearance indicated by its specific name. Of the several species under consideration, this one alone, as I believe, possesses any marked fragrance. Its root-stock is a tuber rather than a rhizome—or such, at least, it appears in autumn, after all the rest of the plant has perished—an ovoid body one to three inches in length, with thick and hard outer shell, covered with bosses quite like a Pine cone in appearance. In this state the plant is prepared to hibernate and endure safely the droughts of the earlier months of the year, when many of the shallow lakes which it inhabits are dried up, and the land, where they lie tumbling about on the surface, is even growing a crop of Wheat.

This strange habit of the plant would seem to favor the success of its cultivation, for its season of growth is but a few months, and when they are matured the tubers can be stored dry as well as potatoes.

Thus, as we see, two white Water Lilies, a yellow one and a blue one gladden the eyes of the botanical traveler in these interesting regions.

San Luis Potosi.

C. G. Pringle.

Plant Note.

Pyrus arbutifolia.

THE two forms of the Choke-berry usually referred to *Pyrus arbutifolia* as varieties have been growing side by side in the Arnold Arboretum for a number of years, and display characters here which seem to make it desirable to regard them as specifically distinct. One of these plants, which must be considered the type of the species as usually limited, is reproduced in our illustration on page 417. It is the plant which Linnæus described in the "Species Plantarum" as *Mespilus arbutifolia*, and which appears to have been one of the earliest North American plants known to European botanists, as it was described by Breyne in his *Prodromus* of the rare plants cultivated in the gardens of Holland, published in 1678. Paul Hermann included it in his catalogue of the Leyden Garden, supplementing his descriptive phrase* by an excellent figure which exactly reproduces the plant of our illustration; and it was described again by Plukenet in the "Almagestum Botanicum," published in London in 1696†. Linnæus quotes the figure of Hermann after his descriptive phrase in the "Hortus Cliffortianus" "*Mespilus inermis foliis lanceolatis crenulatis*," which forms the basis of his description of *Mespilus arbutifolia* in the "Species Plantarum." It is evident, therefore, that if the species is to be divided, the plant of our illustration must be called *Pyrus arbutifolia*, and the common Black-Fruited Choke-berry, first distinguished as *Mespilus arbutifolia*, variety *nigra*, by Willdenow in his "Species Plantarum" (ii., 1021), published in 1799, *Pyrus nigra*. For Willdenow's work was published four years earlier than the *Flora* of Michaux, where it was first described as *Mespilus arbutifolia*, variety *melanocarpa*. Should it on further investigation be found that the two plants are varieties of one species, then the right name for this variety would be *Pyrus arbutifolia*, var. *nigra*.

Characters which appear to separate these two plants are the nature of the leaves, the flowering period, the size of the fruit, and the time of its ripening and falling.

The leaves of *Pyrus arbutifolia* are usually oblong or sometimes oblanceolate, very acute or acuminate, dull yellow-green on the upper surface and densely covered on the lower with thick, whitish tomentum, which is not deciduous. The flowers open in the Arboretum in the early days of June and the fruit does not ripen until the end of October; it is then globular or pear-shaped, and not more than a quarter of an inch across. It is bright scarlet but not lustrous, and remains on the branches without much change of color after the leaves have fallen and until late into the winter. The plants in the Arboretum have reached a height of three feet, with an upright habit of growth, and present a much less leafy appearance than those of the Black-Fruited Choke-berry.

The leaves of *Pyrus nigra* are broadly obovate, generally quite glabrous on the two surfaces even when young, although sometimes pubescent below even at maturity. They are dark green and lustrous on the upper surface, and often nearly as broad as long. The flowers appear in the Arboretum about the 20th of May, and the fruit ripens early in September. It is depressed-globular, very dark vinous purple or black and lustrous, half an inch across or often more, and falls from the branches as soon as it is ripe. The habit of this plant is denser than that of the scarlet fruited species, and is the more ornamental of the two in foliage. It varies considerably in the size and shape of the fruit, and in the size the plant attains. The form with dark, vinous red fruit usually has leaves which are pubescent on the lower surface, while the glabrous-leaved variety has larger black fruit. The fruit of both forms falls as soon as ripe—a constant and important character. The form of the leaves would not sufficiently separate these two

plants specifically, but the difference in the form and color of the fruit, and especially in the length of time it remains on the branches, is so marked and constant that it is hardly possible to unite them.

Pyrus arbutifolia is less common and apparently less widely distributed than the black-fruited plant, although the two grow together in some parts of New England and southward through the Alleghany Mountains. It is not, however, common in any part of the country which I have visited.

Pyrus arbutifolia is one of the most ornamental and desirable of the hardy shrubs which, in this climate, carry bright colored fruit into the winter, and is worth a place in every garden for this character alone.

Our illustration is from a drawing made by Mr. Faxon from a plant in the Arboretum raised from seeds collected many years ago by Mr. A. H. Curtiss in the mountains of Virginia.

C. S. S.

New Orchids.

EPIPHRONITIS × VEITCHII.—This is a very interesting bigeneric hybrid, raised by Mr. Seden, in the establishment of Messrs. James Veitch & Sons, of Chelsea, between *Sophranitis grandiflora* and *Epidendrum radicans*, the latter being the pollen parent. It is very similar to the last named in general character, though much dwarfer, being at present but nine inches high. The flowers are also deeper in color, and borne four or five on a terminal scape. The generic name is compounded from that of the two parents. The plant was awarded a first-class Certificate and also a Botanical Certificate at a meeting of the Royal Horticultural Society on June 24th last. —*Gardeners' Chronicle*, June 28th, pp. 799, 800; July 5th, p. 20.

LÆLIO-CATTLEYA × EXIMIA.—A handsome hybrid raised by Mr. Seden for Messrs. James Veitch & Sons, between *Cattleya Warneri* and *Lælia purpurata*. The sepals and petals are lilac, of good size and substance, and the lip very large and expanded, rich purple with a lilac margin. It was awarded a first-class Certificate at a meeting of the Royal Horticultural Society on June 24th last. —*Gardeners' Chronicle*, June 28th, p. 800.

LÆLIO-CATTLEYA × CANHAMIA.—Exhibited by Messrs. James Veitch & Sons at a meeting of the Royal Horticultural Society on June 24th last, when it received an award of merit. It is said to be a hybrid raised between *Cattleya Mossia* and *Lælia purpurata* and the reverse cross of *L.-C.* × *Canhamiana*. Sepals and petals pale lilac, almost white, the lip mottled with purple. —*Gardeners' Chronicle*, June 28th, p. 800.

SARCOPODIUM GODSEFFIANUM.—This is very closely allied to *S. Dearei*, otherwise *Bulbophyllum Dearei*, though it is said to differ in habit and in some slight floral details. It was exhibited by Messrs. F. Sander & Co., of St. Albans, at a meeting of the Royal Horticultural Society on June 28th last, when it was awarded a first-class Certificate. —*Gardeners' Chronicle*, June 28th, p. 800.

MOOREA IRRODATA, Rolfe.—A striking novelty, and so distinct that a new genus has been proposed for its reception. It is allied to *Houlletia*, of which it has much the habit, but differs in various details of the lip. The flowers are borne in an erect raceme, the sepals and petals spreading, bright reddish brown, passing into nearly white at the base, thus giving a circle of paler color, which is very striking. The lip is three-lobed—the front lobe long and narrow, the side ones large and rounded, bright straw color, with radiating lines of blackish purple; in fact, it resembles a butterfly attached by its head. It flowered in the Glasnevin Botanic Garden, Dublin, under the charge of Mr. F. W. Moore. —*Gardeners' Chronicle*, July 5th, p. 7.

Kew.

R. A. Rolfe.

Foreign Correspondence.

London Letter.

AN exhibition and conference devoted to Ferns by the Royal Horticultural Society was sufficiently supported in every way to warrant the belief that Ferns are in the ascendant with English horticulturists. Those Ferns which may be grown in the open air in England obtained the greatest share of attention, owing partly to the magnificent collections of them exhibited by the few specialists who have made hardy, and particularly British, Ferns a life-long study, and partly to the general ignorance which prevails with regard to these plants. The

* *Sorbus Virginiana*, *foliis Arbuti*, 51, t.

† *Mespilus Virginiana*, *Arbuti lanato folio*, 248.

exquisite beauty and grace of habit with the endless variety of form which belong to British Ferns, as represented in the best collections, astonish even experienced gardeners, who wonder how it is that such beautiful plants are not more generally grown.

English Ferns in their wild forms are charming, but the hundreds of varieties of them which have been got through cultivation, selection and hybridization are simply marvelous. Crested, crimped, contorted, made to develop characters of the most astonishing divergence from the type, these plants

plants thus bred. On the other hand, Mr. Dreury reckons that spores of any sportive variety will produce a considerable number of widely distinct forms without the aid of cross fertilization. The Kew collection of British and other hardy Ferns contains all the best of the varieties raised by Mr. Lowe and the other specialists named. They are planted together on a large rockery and mound, where they form a most interesting feature of the garden.

Tropical Ferns, also, were exhibited in great numbers, and their merits were discussed by eminently qualified men. The

Fig. 52.—*Pyrus arbutifolia*.—See page 416.

have so altered that it is often difficult to believe that they are mere sports due to the skill of the cultivator. Mr. Lowe, Mr. Dreury, the late Colonel Jones and Mr. Carbonnel appear to have possessed the power of obtaining almost any character they liked from a given Fern. Mr. Lowe attributes all these variations to cross fertilization, and so confident is he that Ferns cross quite freely that he professes to be able to obtain by sowing the spores of six distinct forms together a plant which will possess the combined characters of all the six!

This startling statement was almost too much for the physiological botanists, but Mr. Lowe produced his specimens of

horticultural papers here have since devoted much space to Ferns of all kinds. The result of this "boom" cannot but be to bring Ferns of all kinds into prominent notice. The papers read at the conference and the discussions which followed were devoted to the cultural requirements and distinctive features of the best kinds of Ferns as well as to the botanical relationships of the order. An appeal was made for simpler nomenclature, the necessity for which is seen in such names as *Polystichum angulare*, var. *divisilobum plumosum densum*, the name attached to one of the most beautiful of the hardy Ferns shown.

Ivy-leaved Pelargoniums.—The great improvement recently made in this really useful section of *Pelargonium* by Monsieur Lemoine and others is thoroughly recognized in England, where the finest of the newer seedlings are now amongst the most popular of greenhouse plants. By crossing the old kinds with others Monsieur Lemoine obtained new breaks, which retained the loose habit and ivy-like foliage of the old forms, but instead of the small loose trusses and dull colors of the flowers which characterized them, the new seedlings have trusses as large and colors almost as varied and bright as those of the best of the Zonal section. A few days ago I saw a very fine collection of these new Ivy-leaved kinds at Chiswick, where they are exceptionally well grown, some of the specimens being quite a yard through and bearing scores of large flower trusses. The best of those noted were the following: Abel Carriere, large flowered and bright cerise in color; Bridal Wreath, white, with a few spots of rose; Charles Turner, a rich rosy carmine; De Quaterfages, large, rich red, with a tinge of violet; Madame Crousse, Madame Thibaut, Emile Lemoine, Le Printemps and Isidore Feral; these are all remarkable for the size and substance of their flowers and their clear, attractive colors. If it be true that all the Ivy-leaved *Pelargoniums* known in gardens are the progeny of *P. peltatum*, touched with forms of *P. zonale*, one cannot but wonder at the extraordinary improvement wrought by breeders in this one section of the genus.

Lilium Wallichianum.—The variety *Superbum* of this fine Indian Lily, introduced a year or two ago by Messrs. Hugh Low & Co., is much superior to the type, both in regard to vigor of constitution and the size and beauty of its flowers. It is now flowering at Kew, a bulb which last year had but one stem bearing three stems this year, each with three or four flowers, which are as large as those of the Bermuda Lily (*L. Harrisii*), but creamy white, with the inside of the tube colored canary yellow. This is the plant of which a colored plate recently appeared in *The Garden* under the name of *L. ochroleucum*, a name which used to belong to the species now known as *L. nepalense*. Hitherto *L. Wallichianum* has been known as a refractory garden plant, but the variety, at all events, has so far proved perfectly amenable to cultivation here.

Humea elegans.—A short time ago there appeared in an Australian publication a figure and notice of a form of this plant which in some part of Queensland attained a height of about twenty feet. Seeds of this variety were obtained for Kew, and from them plants were raised which are now ten feet high, and have not yet shown any disposition to bloom. By the side of them are some of the ordinary form of this plant, the two kinds having been grown together from the commencement. The latter are, however, now covered with their elegant plumes, and are nine feet high. There is a marked difference in the foliage of the two kinds, the Australian form having much broader, longer, less acuminate leaves, the base more markedly decurrent, whilst the stem is covered with a thick coat of felt-like white wool. It is possible that this may prove a new species, but whatever it may be it is certainly a very striking plant, and if it can be got to flower under cultivation in England it will be quite sensational.

Rehmannia rupestris.—This is another of Dr. Henry's discoveries in western China, and of which plants raised from seeds taken from dried specimens are now in flower at Kew. The genus *Rehmannia* is composed of about six species, all natives of China and Japan. It is closely related to *Digitalis*, but its appearance suggests *Gesneraceæ* rather than *Scrophularineæ*. One species—namely, *R. glutinosa*, generally known as *R. Chinensis*—has long been known in England as a hardy herbaceous plant. It is figured in the *Botanical Magazine*, t. 3653, and in the last number of the *Gardeners' Chronicle*, from a plant grown in a sunny border at Kew. The new one is about eighteen inches high, the central growth erect, the laterals all drooping. The leaves are large, ovate, fleshy, toothed and thickly covered with silky white hairs, giving the whole plant a silvery appearance. The flowers are not unlike those of the Foxglove in shape, and they are white, tinged with rose; they are produced singly from the axils of the leaves. Grown in pots this plant is pretty enough to please, and should it prove hardy it will be a useful acquisition as a front-row plant for the herbaceous border. Mr. Hemsley, who described this species in his "Index Floræ Sinensis," quotes Dr. Henry's note to the effect that in China this plant is known as Cliff Cabbage, and that it is much esteemed as a medical simple. It is said to grow in almost inaccessible places on the faces of cliffs. At Kew it has grown well planted in a roomy pot in rich soil.

Campanula Vidalii is one of the handsomest greenhouse plants in flower at Kew. It is quite distinct from all other

garden *Campanulas* in its shrubby habit, the main stem developing a head of about a dozen sturdy semi-erect branches, each a foot long, and clothed with oblong, fleshy, dark green, glossy leaves, and from the end of each of these branches is pushed a long, erect spike of waxy white flowers. After once flowering the plants are done for, as they never again make good, shapely plants. Seeds are ripened freely by cultivated plants, and from these it takes three years to produce a full-sized flowering specimen. Cuttings never grow into good plants. The species is a native of the Azores, and it is figured in the *Botanical Magazine*, t. 4748.

Cultural Department.

Training up an Orchard.

IT is not very difficult to prepare the land and set out 500 or 1,000 young Apple-trees. By this I do not mean that such work can be well done without much knowledge and considerable practical experience. The selection of trees from the nursery, the choice of varieties suitable to the locality and the market, the due preparation of the ground and the practical work of setting out the trees, all require knowledge and skill, for lack of which many orchards are more or less failures.

But when all of these beginnings have been well accomplished, not much more has been done toward a successful and profitable orchard than is done when we equip a son with the supposed requirements for entering college. We have a young orchard before us, and our duty is to keep each tree in the best shape and condition, so that when it begins to produce fruit it will not begin to show defects and suffer injury. Correct pruning is the first requisite of success, and it should be mainly knife-pruning—that is, a good orchardist will not allow any limbs that must finally come out to reach a large size.

One who thinks this a small undertaking will find himself mistaken. To keep an orchard properly pruned requires a well developed imagination. The orchardist must be able to see his trees in the mind's eye, as they will appear in three, six or twelve years. But to know how they will look implies a knowledge of the habits of growth of the different varieties under culture. So it might be said that an orchardist needs to spoil one orchard before he can know how to direct the growth of a second. It is only when the beginner has had the advantage of training under an expert that he will be likely to succeed at the first attempt.

The Apple has been so long under cultivation that very wide variations exist in its habits of growth. It is likely, also, that among our numerous varieties there exists considerable hybridity. We have not yet been able to produce any hybrids between the European Apple and our native species, and Professor Budd's experience seems to indicate that it will be a difficult task. But there is good reason to believe that the Apples of Europe are not all descended from a single species. Many of the recently imported varieties from Russia show remarkable distinctions from the older sorts, not only in habits of growth, but in microscopic differences in the structure of their leaves. It is being remarked, also, that they have, as a class, a more vigorous inflorescence, and that the texture of the flesh, and the flavors of these fruits, are more or less characteristic. In this country hybrids, both accidental and worked, between our old stock and the Siberian Crabs, have been produced and are in fruit in various localities.

Now all these matters affecting the habits of growth in so widely separated varieties are important to be known, before we can form a true conception of the work of pruning a young orchard and giving to each tree its proper form.

But the forming of the tree is only a single division of the task. We must know much about the habits of and means of checking and destroying the many insects, quadrupeds and birds which will interfere with our work. Unless these vermin can be promptly subjected and controlled, we may find our young trees much more than decimated at any time. Mice have been known to destroy hundreds of trees in one orchard in a single winter—gnawing the bark from the ground up into the larger limbs. There are remedies for a moderate amount of this barking by rodents, but a tree once thoroughly girdled by them is a hospital specimen forever after, no matter how skillfully treated. Bark lice come, sometimes, as though blown in clouds through an orchard, and only the most active treatment will subdue them. It is the same with the attacks of aphids, the tent and forest caterpillars, the web worms, the rank worms, and the borers. In short, the orchardist of the greatest skill and experience is many times "put to his trumps" successfully to meet emergencies and maintain the thrifty and uniform growth of his trees.

One of the Sacred Olive-Trees of Blidah.—See page 414.

All these things being successfully attended to, there are yet other matters equally important. The cultivation and fertilization of the soil of an orchard requires skill and knowledge. That the land should be first thoroughly put in condition before the trees are planted, is assumed at the start. But what shall be done with it while the trees are advancing toward the age of profitable bearing? What crops may be grown in a young orchard without injuring it, what manuring will it need and what shall be the method of tillage?

It may be set down as a positive rule that grain crops of any sort ought not to be grown in a young orchard. If a fundamental guiding principle is wanted, let it be that whatever crop is planted among fruit-trees must be one that will make its growth mainly after the trees have made theirs. In my own experience I have found Beans to be the best. They are not planted until the trees have made considerable growth, and do not draw much on the land before their terminal buds are formed. They come off early and allow of the superficial

cultivation necessary to destroy weeds. They need only shallow plowing and working, so that the roots of the trees are not much injured; and finally, the straw makes the best of all mulch for the trees, inasmuch as there is nothing in it to attract mice, it is not easily scratched about by fowls, it decays slowly, and when decayed makes a very rich dressing, as shown by the free growth of trees thus treated.

As to the amount of growth desirable in a young orchard, I think it should not be less than one foot annually, and that this must be maintained, where necessary, by a sufficient manuring. This may be either with stable-manure or any complete commercial fertilizer. Manuring sufficient to give a vigorous growth of Beans—yielding a crop of twenty bushels or more to the acre—will keep the trees growing just enough. An occasional dressing of ground bone and wood-ashes, at the rate of 1,000 pounds to the acre, always shows itself in giving vigor to the growth of the trees and a deep, healthy color to their foliage.

Newport, Vt.

T. H. Hoskins.

Notes on American Plants.

Hydrastis Canadensis (Orange-root or Yellow Puccoon) flowers early in May, but the flowers are not showy, and they come at a season when there are plenty of others. But the foliage is fine, and it is a pretty plant when in fruit. Its height is only about a foot, and the three large cordate leaves are from five to eight inches wide, deeply several-lobed, and they remain fresh and green nearly the entire season. It is valuable for shady situations, especially when a low foliage plant is needed. It needs a light soil. It is perennial, and when once established forms a thick and permanent bed.

Silphium terebinthinaceum (Prairie Dock), which blooms about the middle of August, is a showy and stately plant, from four to eight feet high, with numerous bright yellow flowers, two or more inches wide, and large radical leaves, often eighteen inches long by a foot wide, besides the long petioles. It is a member of the Composite family, common on prairies from Michigan and Iowa south to Georgia and Louisiana. It does well in any ordinary garden soil in the sun or a thin shade. It is a near relative of the Compass-plant (*S. laciniatum*), which has once or twice divided root-leaves and similar yellow flowers, and which in favorable situations sometimes attains a height of twelve feet, and comes into flower a little before the former. Both are desirable, but need more time to become established and attain their full size than most plants.

The Climbing Hempweed or Boneset (*Mikania scandens*), which is not rare in moist places along the margins of streams and borders of ponds from New England to Texas, climbing over shrubs or anything else by which it can hold itself up, flowers about the middle of August, and is a pretty climber for such moist places. It is a herbaceous perennial belonging to the Composite family. Both the foliage and small heads of purplish flowers are handsome. It comes readily from the seed or may be transplanted.

Another member of this same order, but not a climber, and which blooms a little later, is the *Artemisia Canadensis* (Sage-bush or Mugwort). The flowers are not conspicuous or showy, but its fine and abundant silvery foliage is very handsome. When stimulated by cultivation the plant spreads out over a large space. The stems are weak and half trailing, and so numerous that a single plant will cover a space of three or four feet in diameter if given room enough and a light, rich soil in the sun.

Southwick, Mass.

F. H. Horsford.

Rose Notes.

Rosa rugosa seems to be attracting much attention among the hybridizers of late years, and it seems reasonable to suppose that some advantages may thus be gained. The tough, strong foliage of this plant, and also its free growth, are points in its favor for hybridizing purposes, and it would therefore not be surprising if a numerous race of *Rugosa* hybrids should appear in the near future.

In this class is Madame Charles Frederic Worth (Schwartz), one of the recent introductions, and described as being very vigorous and perpetual flowering, flowers large, full, and well formed, and color carmine-red. If this new-comer justifies the above description it will doubtless prove a valuable addition.

Clothilde Soupert (Soupert and Notting) is a charming little Rose of the Polyantha type, flowering in corymbs which are very freely produced, and the flowers varying in color from deep rose in the centre to almost white on the outer petals. This has been largely propagated as a bedding Rose, and it is now proposed that it be grown for winter cut flowers, as its

small flowers would prove very useful for "filling" in design work.

A serviceable old Rose that has been somewhat neglected of late years is Duchesse de Brabant, possibly on account of the greatly increased list of pink Roses, many of which are larger and of more perfect form than this one. Still it is a plant of good constitution and a vigorous grower, useful either for summer bedding or for winter forcing. The flowers are of medium size, nearly double, and of a very pleasing shade of pink. When the plants are making strong growth the flowers are frequently produced in clusters, though this last characteristic is not always considered an advantage.

Among the dark-colored Hybrid Perpetuals, Alfred de Rougemont takes a prominent place when well grown, its large, fragrant, dark crimson flowers being admirable, and although in commerce for over a quarter of a century, it will still compare well with many of the newer sorts. This variety is also useful for forcing if not forced too early in the season, at which time it is very shy in flowering. This variety should not be confounded with Madame Alfred de Rougemont, which is a Hybrid Noisette of comparatively inferior quality.

Another of the older hybrids which should have a place in every collection of Roses is Marie Baumann, a variety of charming color and delightful fragrance. Its color may be described as carmine-crimson, or rather crimson shaded with carmine. The flowers are full and of fair size, the foliage and growth are strong and free, and altogether it possesses a combination of good qualities which it is hard to excel. Marie Baumann is also a good forcing variety, though the flowers sometimes have a finer color when grown in the open air than when under glass.

As a pillar Rose or for training along the roof of a cool conservatory, the old Noisette, Lamarque, is a first-rate variety, and when properly treated it produces immense crops of its large white flowers, while its bold foliage and strong growth are additional points in its favor. It is also an excellent stock upon which to graft Niphetos, the latter producing particularly fine flowers when thus treated; and while the grafting process may not be absolutely essential to the welfare of Niphetos, yet it certainly does appear to increase its vitality to the extent of making it produce heavy winter crops of flowers for a long series of years, at least when the stock used is Lamarque.

Very favorable reports have been given of the "Climbing Perle des Jardins," it being stated that the flowers are equal to and as freely produced as those of the type, while the growth is strong and vigorous and the foliage handsome, the distinctive feature being its scandent habit. It would therefore appear that a valuable addition had been made to the list of climbing Roses for in-door use at least, as in all probability it is no more hardy than the parent variety. Perle des Jardins sometimes endures full exposure to the winter in the vicinity of Philadelphia, but such treatment is not usually justified.

Holmesburg, Pa.

W. H. Taplin.

The Narcissi and their Culture.

THE question is often asked whether it is necessary, or even desirable, to lift the bulbs of Narcissi annually and replant them? My reply has invariably been in the negative. Last fall circumstances necessitated the lifting of a large collection of these plants, including all the common and well known kinds, besides a quantity of choicer varieties of garden origin. Some of these were planted immediately, before the bulbs were the least dried from exposure, while others were kept in barrels and planted later. In their old quarters the bulbs had been planted three years, and we found on lifting them that those sorts which increased rapidly from offsets were really in need of lifting, as the bulbs were so crowded as to render it next to impossible for them to develop properly. This was the case with all of the Poeticus section, and others of strong constitution, such as Sir Watkin, Horsfield's and Princeps. Others, again, had not multiplied to any great extent, and, to all appearances, would have done well another three years without being disturbed. The bulbs were planted nine inches deep and covered with earth enough to bury them, and then good, well decayed manure was placed on the soil to a depth of one to two inches, and the remainder of the soil filled in. The loss from removal was small, and could be traced in most cases to a subsequent disturbance of the soil for the purpose of lifting bulbs, which brought the manure in direct contact with those left in the soil. Taken altogether, the growth this spring was not so strong as in past years, though the flowers were quite as numerous, these, of course, being formed in the bulbs previously. It may be taken for granted

that, unless clumps or beds of *Narcissus* have become crowded, it is by no means necessary to lift them at all, provided that, in common with all other permanent occupants of the flower-border, they receive an annual top-dressing of good manure in fall, the remains of which may be raked off very early in spring, before the leaves appear above ground.

It is surprising that one may visit so many places even among good gardens, without seeing anything like a collection of these loveliest of spring hardy bulbs. I have visited many gardens of late and have seen but one where any other than the commoner kinds were grown, and this was a trial collection; as if it had not been proved again and again that the *Narcissus* adapts itself readily to our eastern climate. One very important point, however, is to plant early, if imported bulbs are procured, for success the first year hinges upon a vigorous root-action before the arrival of frost. It is not too late to transplant, and this is the very best time to plant imported bulbs. It is well to be cautious with new or little known kinds when forming a collection. There are enough well tried varieties which may be relied on to do well, and which include the very best of Daffodils, such as *N. princeps*, an early kind, *N. Poeticus* and its varieties, which are always admired, and by planting with the type several varieties, such as *Angustifolius*, *Ornatus* and *Recurvus* these Poet's *Narcissus* may be had in bloom for six weeks. They flower in the order named, the type following the variety *Ornatus*. *N. maximus* is one of the best kinds, and reliable, being of robust habit. Horsfield's variety is to my mind the best and most distinct of all in cultivation. It forces well and is a general favorite. The varieties known as Emperor and Empress are noble kinds, but not reliably hardy.

The giant Welsh Chalice Flower, however, is perfectly hardy, has immense flowers, and is perhaps the most profitable Daffodil ever handled by the trade, owing to its rapid increase and the growing demand that keeps up the price. Where one bulb is planted three may be dug in a year's time. It is obviously a good sort to have. *N. obvallaris*, the Tenby Daffodil, with its airy appearance, is very early and also forces well. Golden Spur is a kind of recent origin; it is very large, early and of a rich yellow color. The pretty, sweet scented Jonquils, with their Rush-like leaves, should not be neglected. *N. gracilis* has similar foliage with clusters of fragrant yellow flowers, and is the latest flowering variety we have tried; it always blooms in the latter part of May and is quite hardy. Those who have a greenhouse should try the Hoop-Petticoat *Narcissus*. These are easily procured, flower abundantly even when forced, and are known as *N. bulbocodium*. If the soil is of a retentive nature a handful of sharp sand should be placed under each bulb when planted; this assists the young roots to push their way into the soil and acts as drainage to the bulb when at rest.

South Lancaster, Mass.

E. O. Orpet.

The Florists' Convention.

Extracts from Papers Read.

THE annual convention of the Society of American Florists, which was held in Boston last week, attracted a larger attendance than any former meeting. The plan of omitting the afternoon session each day gave such an opportunity for social enjoyment and sight-seeing that the sessions in the morning and the evening were always well attended, the large hall in the horticultural building being filled in every instance. A resolution was passed that at future meetings the exhibitions shall be closed when the Society is in session. This will leave nothing to draw members away from the exercises and will be an additional improvement. The papers read were of a practical character, and the discussions were pointed and business-like. The local florists' club made the visiting members welcome in every way, and by arranging excursions not only in the harbor, but to such interesting places as the grounds of Mr. H. H. Hunnewell at Wellesley and Mrs. F. B. Hayes at Lexington, gave an opportunity of inspecting some of the most interesting examples of the gardener's art that could be found in the country.

The trade exhibits in the lower hall were very interesting. Mr. Chas. D. Ball, of Holmesburg, and Mr. Henry A. Dreer, of Philadelphia, Robert Craig and Edwin Lonsdale had exhibitions of their stock in trade in plants in fine health and grouped with much taste. The Messrs. Pitcher

& Manda also showed a large exhibit of *Cypripediums* and other Orchids, including many choice hybrids and a plant of *Licuala grandis*, which is probably the best specimen of its kind in existence. The exhibits of bulbs, seeds and florists' supplies by F. R. Pierson, Joseph Breck & Sons, F. E. McAllister and others were most attractively arranged, and the display of heating apparatus and other greenhouse requisites in Bumstead Hall was unusually complete and instructive.

Abstracts of some of the more important papers are given below:

THE PRESIDENT'S ADDRESS.

The address of Mr. Jordan was largely devoted to the needs of a higher horticultural education both for the benefit of the florists and of the public. He insisted that the mission of the Society was not only to instruct members in the daily practice of their business, but to increase the general interest in horticulture and to develop a taste for it among the people. To this end all persons interested in the various departments of horticulture, as well as those engaged in researches in any science connected with it, should be invited to assist in this work.

Large fortunes have been bequeathed to religious institutions by persons who, of course, cannot foretell what may be the specific teachings of any sect a century hence. Libraries have been established and schools endowed to carry out some wish of their donors, and yet it must be acknowledged that comparatively few receive the benefit of these endowments when compared with the masses of people, young and old, rich and poor, learned and illiterate, who can take object lessons from parks and gardens. These were no doubt the sentiments which inspired Mr. Henry Shaw to bequeath his immense fortune for the purpose of instructing the people in an ever-growing knowledge of horticulture. By his will a botanical garden is given to the public with means to insure its constant and effective maintenance for the cultivation and propagation of plants and flowers, fruits and trees, together with a museum and a library devoted to the service of botany, horticulture and allied subjects. A school has already been established under the direction of Professor Trelease for young men who are to be trained in the science and art of horticulture. The income of the estate already realizes hundreds of thousands of dollars, and will soon reach the magnificent sum of \$1,000,000 a year. The world can safely be challenged to show a like donation from any one individual.

Mr. Jordan also spoke of the advantages offered by the experiment stations, which are to make a regular business of discovery, to promote investigation and to diffuse the knowledge which improves horticultural practice. The United States Department of Agriculture has arranged to condense the bulletins from the various stations, and they are delivered free to all who see fit to ask for them, so that every one engaged in horticultural pursuits has it in his power to gain useful knowledge by consulting them. He counseled each member of this Society to make the acquaintance of the Director of the nearest experiment station, to furnish him with plants and trees for testing, and to report such facts as may have been learned by him in his business practice. By such an interchange of knowledge the profession will advance to a higher plane, where less drudgery will be needed and where work will be done in accordance with the established laws of science.

The speaker argued that there should be established some standard of qualification for young men entering into the employment of florists to learn the business. The time will soon come when many of our institutions of learning may graduate students prepared to become florists' apprentices. He added that suitable books should be prepared for use in schools which give instruction in the fundamental principles of horticulture, and insisted that even common schools should teach the rudiments of the art.

EXPERIENCE IN CROSSING PLANTS.

Mr. E. S. Carman, editor of the *Rural New Yorker*, read a paper recounting some of the failures he had met and the successes won in this field during seventeen years past. The record of failures is omitted here for the lack of space, although it was quite as interesting as the remainder of the paper, from which we make the following extracts:

In my practice a sharp pair of scissors, a pointed piece of wood (or even a wooden toothpick), a box for the flowers or pollen, sheets of firm tissue paper and a little strong yarn answer every purpose, so far as tools and mechanical outfit are

concerned. A camel's-hair brush is rarely of service. If pollen can be gathered in quantity, as from Rye, Roses, Honey-suckles, etc., it may be placed in boxes and applied from the point of a knife or by placing the ripe anthers themselves in contact with the receptive stigma.

In performing the operation the bud should be opened, the green anthers removed and the bud tied up in close, fine tissue paper. Open it only to apply foreign pollen to the stigmas, and at once again protect them from possibility of contact with any other pollen. If fruits and seeds then develop we are confident that the seeds are cross-breeds.

About fifteen years ago we began crossing Wheats. While engaged in this way it occurred to me to make the attempt to hybridize Wheat and Rye. The result of pollinating many heads was ten seeds, nine of which germinated and wintered safely. Eight resembled Wheat in every way, and the plants scarcely differed from the mother, which was Armstrong, a beardless variety. The ninth plant was peculiar in having hairy culms and long, narrow heads, of which there were about twenty; and these twenty heads were so nearly sterile that they bore only a grain or so apiece. The other plants were all fertile, and several of them were again pollinated with Rye. It would take a long time to recount the suggestive, instructive history of these plants. I have now plants which by blood are fifteen-sixteenths Rye. These were nearly sterile, and all attempts to again cross with Rye have resulted in absolute sterility. Some of the fifteen-sixteenths Rye plants grow more fertile each year. Many of the three-fourths Rye plants are now fully fertile, and so well fixed that we are propagating them for introduction, while three of the half-breeds have already been introduced. Many of the hybrids bear very large kernels, long heads, with close spikelets. Some of them are as early as Rye, and perfectly hardy at my home. Thousands have been destroyed on account of their conspicuous worthlessness.

Some years ago Professor William Saunders, of Canada, told me he thought he had effected a cross between the Raspberry and the Blackberry. We made crosses the next season and every season since. The Raspberry alone was used as the mother plant the first year. Some of the seedlings were Raspberries in every way, some were Blackberries in every way, a few were intermediate. Whether an improved variety will come out of these remains to be seen. Thus far, all that have fruited produce imperfect berries; that is, berries with from one to a dozen drupelets; while others bloom but do not fruit at all. Professor Saunders' Hybrids were from some accident destroyed before fruiting.

We have never raised a Rose from any other seed than that borne by *Rosa rugosa*. This plant is very hardy, bearing leaves of exquisite beauty—thick, leathery, with a glossy, wrinkled surface. The flowers are large, single, and in color white or pink. As a pollen parent we used the first summer Harison's Yellow, and that alone. This is a very hardy Austrian Rose with small leaflets, bearing semi-double yellow flowers. Most of the seedlings died from mildew. Only about thirty survived. When it is considered that *R. rugosa* differs from all other Roses in such a marked way, one would naturally have supposed that its seedlings would be stamped with its peculiar characteristics rather than with those of the male parent, which may be said to resemble, in a general way, a hundred other Roses. Such was not the case. Most of the seedlings resembled the male parent in having small leaflets which were neither wrinkled nor of unusual thickness. The flowers were a yet greater surprise. All the single flowers are small, the colors being rosy white, pink, dark pink. There were neither yellow nor pure white flowers. One bush bears small single flowers, which are a feeble Rose color around the edges, then white and finally yellow about the base. Of the double flowers one bush bears pink flowers, which are as "double" as a Rose well can be. The leaflets show the *Rugosa* blood plainly. Three others bear *Rugosa* foliage. The flowers of two are semi-double, of the color of General Jacqueminot. The third, which during the past year has been propagated for introduction by a leading nursery firm, bears flowers identical in color with those of General Jacqueminot. The color is also the same. It is as nearly a perpetual bloomer as is the mother plant. The leaflets, while preserving much of the thick, wrinkly texture, are larger than those of *R. rugosa*. Would any one have prophesied that a yellow Rose crossed on a single pink Rose would have produced a plant so closely resembling General Jacqueminot?

The next year we used pollen from Hybrid Perpetuals, and the next, as well as the present, season from Yellow Teas chiefly. Of these none that have bloomed are yet worthy of remark; we have about 300 in all. The present season

has been specially favorable to an abundant harvest of hybrid seed; probably we have no less than 3,000.

When the hardy and distinct characteristics of *Rosa rugosa* are considered, one would suppose that the children of such a rugged mother would be healthy and strong. The fact is, however, that nine-tenths die of mildew. It is worthy of remark, also, that not one seed in ten is viable. They are shells without embryo.

Finally, you have all heard of the Great Japan Wineberry. Though this is the old *Rubus phanicolasius*, which has been in certain nurserymen's catalogues and in private collections for a dozen years, it is still a most remarkable Raspberry, worthy of a place in every collection. The forming berry is enclosed within the sepals, which are covered with purple viscid hairs, like the bud of a Moss Rose. This protects the fruit from worms, for all small insects are caught and held by the sticky exudation. As the berry ripens, the sepals fall back. The berry, at first a bright, diaphanous scarlet, turns, as it ripens, to a rich ruby color. The berries are juicy and of a refreshing, sprightly quality, with scarcely a trace of the peculiar Raspberry aroma. Upon this we have succeeded in crossing both the Blackberry and the Rose.

SPECIAL FERTILIZERS UNDER GLASS.

Professor S. T. Maynard, in a paper on this subject, began by saying that the three essential conditions for the successful growth of plants under glass are these: the proper amount of water, a temperature suited to their growth and an abundance of plant food. All of these conditions are necessary, and it is difficult to say whether one is more important than another; but the last condition, that of plant food for greenhouse crops, was alone to be discussed.

In making up the soil for greenhouse plants, whether grown in pots or beds, the principal ingredients are: turf, more or less decomposed, or garden soil, and stable manure either fresh or decomposed, according to the nature of the plants to be grown. With these materials properly put together, very successful results are generally obtained by the skillful gardener; but sometimes, either from poor quality of the manure used, from a poor mechanical condition or from improper treatment after being put into the beds or pots, plants fail to make the vigorous growth we desire. Then it is difficult to get enough plant food into the small space of the flower-pot or bench; a small amount of soil and root space being necessary to secure an abundance of bloom. In houses naturally moist we must use a small amount of soil to secure a healthful condition for the growth of the roots; and therefore we must find something to increase the food supply in the soil and to give the plants a start. This has led to the use of liquid made from stable manure. Green manure is placed on the surface of the bench or pots and plant food is washed into the soil by a liberal supply of water. Plants grow well under this practice, but the manure is offensive and requires a great amount of labor and care in its application. We believe that the necessary supply of plant food may be more easily and safely obtained from chemicals and special manures.

After the mechanical conditions have been made right, there is little danger of getting the soil too rich for the common commercial crops, if all the elements of plant food necessary for a complete and perfect growth for the purpose desired are present; that is, if a leaf growth is sought for, potash and the nitrogenous elements must be used, while if seed or flowers are desired, the use of phosphoric acid in the form of fine bone or bone black is recommended.

After the crop has been started, one of the best ways to furnish additional plant food is in a liquid form. The soluble chemicals, however, like the potash salts and the soluble nitrates, must be applied with care; for if the liquid is allowed to remain for a considerable length of time on the foliage it is liable to be seriously injured. The so-called flower-foods and the standard commercial fertilizers of various manufacturers have been very successfully used. For house plants, when the grower is not skilled in the preparation of soil for the perfect growth of plants, the flower-food gives excellent results.

Professor Maynard then gave the details of several comparative experiments in growing Carnations, Pansies, Lettuce and Cabbage plants under glass with various special fertilizers. It is not necessary to give these in full, although the complete tables in which the effect of the various fertilizers were used singly and in combination would be very instructive. The summary of the whole matter is given in Professor Maynard's own language as follows:

Summing up the results of these various experiments we come to the conclusion that, of the nitrates, the sulphate of ammonia gives the best results; that of the potash and soda

salts, the sulphate of potash has given by far the best results. Bone black, in view of these tests, must be given the first place in hastening the maturity of plant growth and in the production of seed, while the nitrate of soda seems to be injurious rather than beneficial. These, however, can be given only as the results of a comparatively limited series of tests; and all careful experimenters know how difficult it is to be sure that all the conditions are fully understood and how unsafe it is to draw conclusions from anything but a long series of experiments. But having taken every precaution to fully understand all the conditions and to make very careful and complete records, and as the results confirm the opinions of some of our best scientists, we feel warranted in recommending, as special fertilizers for greenhouse crops, sulphate of ammonia, sulphate of potash, ground bone and dissolved bone black.

The fact that the nitrate of soda has a tendency to absorb moisture is sufficient to account for the increased amount of mildew and the poor growth of the Lettuce in one plot in both experiments. Why the muriate and nitrate of potash have given no better results must be explained by one who is more of a chemist than I am.

Dried blood and other animal nitrogenous substances are very unsatisfactory in the greenhouse, because of the amount of moisture and animal life they produce in the process of decay.

Potash and other salts must be carefully used and only in small quantities at a time, as in the evaporation of the water from the soil the salts are deposited upon the surface, and, where the tender leaves come in contact with it, they may be seriously injured. Many a batch of seedlings and cuttings has been destroyed in this way, and conditions favorable for fungus growths produced in the tissues of the injured foliage.

Whatever may be your opinions of the results of these experiments, I wish to urge you to give them careful consideration, to repeat them, to verify them and to make other experiments, carefully recording all conditions and results, and to report them at future meetings or to your favorite paper. The value of any new method of cultivation or fertilization must be finally determined by the practical gardener, who is making his living by his labor; and he and the man of science should work together—the one making known his needs, and the other working, in the light of science, to present new truths and to make the practice more easy and profitable.

HELLEBORES FOR THE COMMERCIAL FLORIST.

William Falconer, of Glen Cove, Long Island, read the paper which follows on this subject:

We have two sets of Hellebores—namely, Christmas Roses and Lenten Roses. The Christmas Rose (*Helleborus niger*) and its varieties bear large white flowers in November and December. The Lenten Roses are represented by *Helleborus Olympicus*, *H. Colchicus* and *H. orientalis*. They have purple flowers, while some of their varieties and hybrids have white, purple and spotted flowers, and they come into bloom between January and April.

Christmas Roses are useful as cut flowers, and in pots, if in bloom, they are excellent for house decoration. The Lenten Roses are only useful as pot plants; but both would be classified as "fancy" rather than as staple articles. Florists who have a good local trade can use Hellebores to advantage, but it would be hardly advisable for florists who grow flowers for the wholesale market to handle them.

For cut flowers *Helleborus niger maximus* is the best, but the blossoms must be cut just as wanted for use, for they have no great lasting qualities. One of our leading Boston florists who has handled these flowers writes: "I am a little in doubt about their value as cut flowers. Those I had last winter did not come up to my expectations in keeping qualities, being inclined to hang and droop their heads too much. As pot plants they will give much better satisfaction. The demand at first will be limited and it will grow slowly; still the flower is one that it will pay to grow as a desirable novelty." A New York florist writes: "There is no doubt that *Helleborus niger maximus* and the larger-flowered varieties of *H. niger* would be profitable for cut flowers if large established plants were planted out in a cool greenhouse or a well protected cold frame. The great difficulty, however, lies in the first cost of these large plants, and secondly, in the fact that, as a rule, a florist wants to get immediate return for his investment, and will not wait four or five years or until his plants become large enough to produce an abundance of blooms."

My own opinion of these Christmas Roses is that they are a most welcome addition to our cut flowers, and particularly valuable as they come in at a time when variety as well as quantity is somewhat limited.

As pot plants the Lenten Roses are very desirable, but they need to be strong plants and well grown. Neither the Christmas Roses nor Lenten Roses can be grown profitably as outdoor hardy perennials. They need cool greenhouses or frames. The Christmas Roses should be planted out permanently, and for this reason I prefer growing them in cold frames. As the Lenten Roses are pot plants they may be plunged outside in cold frames in summer, and brought indoors in winter, or, if wanted for late work, kept out in the frame till they show signs of blooming, and then brought indoors. They all prefer a well drained loamy soil, with a loose surface and a somewhat shady place in summer. A frame up against a north or north-west facing wall of a building is a good place for them; or they can be grown under a high-raised lath or brush-shading, such as is used over forest-tree seed-beds. The ground about them should be mulched with half-rotted leaves and finely chopped sphagnum moss, and this keeps it cool, loose and moist all summer.

A Baltimore delegate explained the workings of a florists' exchange in that city which was organized last year under the State laws, and is governed by seven directors—four growers and three dealers. The prices are set by the officials of the exchange, unsold flowers are destroyed and the losses are borne by the exchange members in proportion to the amount of stock they hold. The commission the exchange makes pays the salary of the manager and necessary expenses. The system is said to work well and to give an opportunity for growers to dispose of small lots which a commission merchant would hardly care to be troubled with.

In response to the inquiry "What twenty native plants are the best for florists' use," Mr. A. Gilchrist, of Toronto, Ontario, submitted the following list: *Trillium grandiflorum*, *Cypripedium spectabile*, *C. parviflorum*, *C. pubescens*, *Asclepias tuberosa*, *A. incarnata*, *Euphorbia corollata*, *Coreopsis lanceolata*, *Helianthus strumosus*, *Spiraea lobata*, *Nymphaea odorata*, *Thalictrum Cornuti*, *Rudbeckia laciniata*, *Rudbeckia hirta*, *Eupatorium ageratoides*, *Solidago Canadensis*, *Aquilegia Canadensis*, *Lobelia cardinalis*, *Monarda didyma*.

In reply to the question, What are the twelve best hardy shrubs for florists' use? Mr. Jackson Dawson gave the following list as the best among those that are rarely or never forced for market: *Andromeda speciosa*, *Cytisus scoparius*, *Viburnum plicatum*, *Staphylea Colchica*, *Deutzia Sieboldii*, *Exochorda grandiflora*, *Pyrus baccata floribunda*, *Rubus rosiflorus*, *fl. pl.*, *Weigela candidissima*, *Philadelphus latifolius*, *Spiraea Cantoniensis*, *fl. pl.*, *Kalmia latifolia*.

The following officers were elected for the ensuing year: President, M. H. Norton, Boston; Vice-President, John Chambers, Toronto; Secretary, W. J. Stewart, Boston; Treasurer, M. A. Hunt, Terre Haute, Indiana. It was voted to hold the next annual meeting at Toronto.

Exhibitions.

The Horticultural Show at Boston.

THE annual exhibition of the Massachusetts Horticultural Society, held while the Convention of the Society of American Florists was in session, was conspicuously good in all its details, and was considered by many of those whose judgment is of value in such matters as the best display of the kind which has been seen in this country for years. The exhibition was held in the large Music Hall, and yet the collections occupied so much of the floor space, including stage and galleries, that the throng of visitors had extreme difficulty in moving about without injuring the specimens which skirted the various groups, and even then it was found necessary to pack many of the plants so closely together that large numbers of the very finest of them could not be seen to good advantage.

The exhibition began outside the doorway with a collection of conifers, containing fifty-six species and varieties, from Mr. J. W. Manning, and with similar groups within the vestibule from the Messrs. Temple & Beard and Wm. C. Strong. Some fine specimens of Hydrangea with blue flowers, from Mr. John L. Gardiner, added interest to these outside groups. The view from the stage was almost bewildering. The ample balustrades in front of the balconies were festooned with greenery, with large specimens of *Nepenthes* hanging beneath. Masses of cut flowers made a brilliant appearance in the lower balcony, while in room-like apartments below the balcony and opposite the stage were a number of elegant table and mantle decorations. Under the shade of some immense Palms in the centre of the room was a blaze of bloom from gorgeous

aquatics, while all around the main floor were groups of plants from the best known collections in the vicinity of Boston. In the centre of the stage was a magnificently colored specimen of the Croton, Queen Victoria, exhibited by Mr. George A. Nickerson, of Dedham. Behind it were tasteful groups of foliage plants from the establishments of Mr. F. Becker and Mr. W. E. Doyle, of Cambridge, while about the great Croton were some remarkable plants, among them the highly decorative *Dasyllirion acrotrichum* and large specimens of *Akamanda* and *Agapanthus*, and some magnificent *Fuchsias*, including a fine plant of the variety *Gloria*, well known forty years ago, but now rarely seen here.

Our limits of space will only permit a mention of some of the most meritorious of the plants in the various collections upon the floor, and no doubt among the great number of those represented many good specimens escaped attention altogether. The first group to demand attention was that from the Botanic Garden of Harvard University, which contained excellent specimens of *Gymnogramme calomelanos*, *G. Tartarica*, *Sanseveria Zeylanica*, *Peperomia arifolia*, with choice *Adiantums*, *Selaginellas* and *Marantas*.

Adjoining this was the extensive rich collection of Mr. Nathaniel T. Kidder, including such well-grown specimens of *Cycas revoluta* and *Araucaria excelsa* as are rarely seen. A large plant of *Davallia Mooreana* was greatly admired, as was one of *Cyanophyllum magnificum* and another of *Spherogyne latifolia*. Here also was a fine specimen of *Phyllotanium Lindenii*—a plant whose popularity is evidently on the increase, since it occurred in no less than six other collections.

In the large group furnished by Mr. John L. Gardiner, and arranged with great taste by Mr. Atkinson, were splendid examples of *Gymnogramme schizophylla*, *Adiantum Farleyense*, with remarkable *Marantas* and *Pandanads*.

Noteworthy in the large assortment from the gardens of Mr. H. H. Hunnewell were: *Ficus Parcellii*, *Cissus discolor*, *Croton pictum*, *Dracana indivisa*, *fol. var.* (a particularly elegant variety) and *Davallia Fijensis*.

The collection of Mr. F. L. Ames was so notably good throughout that it is difficult to single out one specimen for special mention, but *Lomaria gibba*, *Platynerium Hillii*, *Anthurium Waroqueanum*, *Croton Mortii*, *Dieffenbachia Bausei* and *Anthurium Veitchii* seemed particularly interesting.

Some grand plants were shown by Mrs. J. Lassell, of Whitinsville, Massachusetts. Specially noticeable were the specimens of *Heliconia aurea striata*, a grand plant for decoration, and one which must soon come into general use, *Alocasia* species, *Dracana Youngii*, and *Gleichenia Mendeli*, a plant of splendid proportions. Two specimens of *Peristeria elata* attracted much attention, and they were worthy of it, for one of them bore no fewer than twelve spikes, one of which had seventeen fully developed flowers and as many more partially developed.

Specimens of *Phoenix rupicola* and *Kentia Belmoreana*, shown by Mr. George A. Nickerson, were among the noblest plants in the whole exhibition.

Some fine Orchids were contributed by Messrs. Siebrecht & Wadley, of New York, and the collection of Mr. Ames was exceedingly rich and varied, containing a great portion of the best plants in bloom at this season. It would be difficult to find better plants of *Lælia crispa superba*, *L. elegans Littleana*, *L. callistoglossa*, *Cypripedium Morganæ*, *C. wnanthum*, *C. bellatulum*, *Odontoglossum grande* and *Cattleya Eldorado*.

Among miscellaneous plants the Harvard Botanic Garden contributed collections of Cacti, with economic and interesting plants; Mr. Smith, of the Washington Botanic Garden, a large collection of carnivorous plants; Mr. R. H. White, a flowering specimen of *Monstera delicosa*; Mr. Benjamin Gray, specimens of the Papyrus, and Mr. David Allen, a remarkable group of Anthuriums. Among the aquatics the cluster of Egyptian Lotus from Mr. Sturtevant's famous pond in New Jersey attracted much attention. Mr. L. W. Goodell had a most complete and beautiful collection. It contained specimens of twenty-five highly desirable water plants, with the information that they were all hardy.

Among the principal awards made were the following: Mr. H. H. Hunnewell received the first prize for Palms, for greenhouse plants, for Caladiums and for Dracænas; Mr. N. T. Kidder, for Ornamental-leaved plants, Ferns, Adiantums, Lycopods and Crotons; Mr. F. L. Ames, for Orchids, for the best single Orchid (*Lælia crispa*), for specimen ornamental-leaved plant and Nepenthes; Mr. John L. Gardiner, for greenhouse plants and Nepenthes; Dr. C. G. Weld, of Brookline, for specimen Tree-Fern, Crotons and Gloxinias; Temple & Beard, for coniferous trees and hardy herbaceous flowers; Mr. O. A. Ruggles, for the best floral design; Mr. David Allen, for the

best mantel-piece decoration; Mr. L. W. Goodell, for aquatic plants and flowers. A silver medal was awarded to Geo. A. Nickerson, for the Croton Queen Victoria, and one to G. McWilliams, for a remarkable *Alocasia*.

Notes.

The journal of the Japanese Horticultural Society states that the exports of plants, trees and shrubs from Japan during the month of January last amounted in value to very nearly \$6,000.

A sketch of the life of Reichenbach, the great authority on Orchids, written by his executor, Dr. Dilling, and originally printed in a periodical, has recently been issued in pamphlet form by Lucas Graefe, of Hamburg.

In a recent number of the *Revue Horticole* Monsieur Charles Naudin states that about eighty species or well-marked varieties of Eucalyptus are now growing in the gardens of the Villa Thuret at Antibes, while several additional species may be found in adjacent localities.

The *Revue Horticole* names as "the horticultural marvel of the year 1890" a new Wistaria (*W. multijuga*), which has bloomed in abundance in the gardens of Monsieur Bertin at Versailles. "Although introduced long ago," adds the *Revue*, "it is hardly known even to botanists, and has been almost impossible to find." It greatly resembles the ordinary Chinese Wistaria, but nevertheless differs from it in ways which the *Revue* promises to explain with fullness at a future time. Meanwhile it is noted that its flower-clusters measure from thirty to forty inches in length.

The American Association of Cemetery Superintendents held its annual meeting in Boston while the Florists' Convention was in session. More than sixty members were present from all parts of the country, and the papers and discussions, which related to all parts of the management of cemeteries, were unusually interesting. The discussions seemed to show that public taste is tending toward a limitation of stone-work, and a stronger reliance upon planting, for general effect. The use of hedges, coping and other conspicuous separations between lots was pretty generally discountenanced, and opinion favored an open, natural treatment of burial-grounds rather than the more rigid and architectural method which once prevailed in cemeteries, and which has its most conspicuous representative now in Greenwood. Mr. John G. Barker, Superintendent of Forest Hills Cemetery, was elected President for next year; R. D. Cleveland, of Lakewood Cemetery, Minneapolis, Vice-President, and Frank Higgins, of Woodmere Cemetery, Detroit, was made Secretary and Treasurer. Mr. O. C. Simonds, of Chicago, was elected Chairman of the Executive Committee. Instructive papers were read by William Solway, of Cincinnati, on "What Trees to Plant and When to Plant Them"; by Mr. O. C. Simonds, of Chicago, on "Shrubs and Trees"; Mr. A. W. Blaine, of Detroit, on "Mistakes in Cemetery Management"; Mr. George Troup, of Buffalo, on "Cemetery Roadways," and Mr. Frank Eurich, of Toledo, on the "Life and Service of Adolph Strauch," the originator of the so-called Lawn System in cemetery design and management.

Experiments in spraying Peach-trees for the Curculio with London Purple resulted last year, especially in the Peach-region of Michigan, in great injury to the foliage, so that Professor Cook in a station bulletin declared that the foliage of the Peach-tree is especially susceptible to injury, and that London Purple is more injurious than Paris Green, owing to the fact, no doubt, that the soluble arsenic is abundant in London Purple and almost absent in Paris Green. Experiments at Cornell made for two seasons seem to corroborate this view, and from a recent bulletin by Professor Bailey it appears, without going into details, that leaves sprayed by London Purple were found to contain arsenic in the texture of the leaves, while those injured by Paris Green showed none. The poison in the latter case simply affected the surface of the leaf. Undoubtedly the injury is caused by the fact that over fifty per cent. of the arsenite of calcium in London Purple is soluble in water, and is thus carried into the body of the foliage. Young leaves are proved to be less liable to injury than full grown ones, which is due, it is supposed, to the wax covering so abundant on recent leaves and shoots. Microscopic examination shows that the Peach-leaf is a very delicate structure, the epidermis being remarkably narrow and the cell-walls thin. This delicacy of structure seems to account for the greater susceptibility of the Peach-leaf to injury than the leaves of the Plum and other trees. A mixture of one pound of Paris Green to 300 gallons of water, when applied in a fine spray, did not injure the Peach-trees. Probably one pound to 350 gallons would be always safe.

The Flowering Dogwood.

THE trees called in popular language Flowering Dogwoods give a peculiar charm to the forests of North America. There are two of these trees, and their counterpart is not found in any other part of the world. In early spring one of them enlivens the deciduous forests of south-eastern America, and the other lights up the gloomy Pines and Firs of the far north-west.

We will glance first at the floral structure to which these plants owe their peculiar beauty. The flowers of the Cornel are individually small, and green or greenish white or white in color. They are arranged in some species in close heads, and in others in open, flat, spreading cymes. The last is the more common arrangement, and the flower-clusters of some of the American species in which the flowers are grouped in this fashion are very beautiful, especially those of *Cornus circinata* and of *Cornus alternifolia*, the former a good-sized shrub, and the latter a small tree or tree-like shrub, of the north Atlantic forests. In those American species in which the flowers are placed in a close head the flower-cluster is surrounded by four or five large leaf-like bracts which enclose it in the bud. These open before the flowers expand and soon begin to enlarge. At this time they are of a rather dirty greenish white color and not more than a quarter of an inch long. They grow rapidly, and at the end of ten days or two weeks are one and a half or two inches long on the eastern tree, or sometimes twice that length on the Pacific coast species, and pure snowy white. To these large showy bracts or floral leaves the Flowering Dogwoods owe their name, and not to the flowers, which are very small, of a pale greenish color, and quite inconspicuous.

The fact that the vernal beauty of these trees is due to leaves and not to flowers lengthens the time of what is popularly supposed to be their flowering period; for the floral leaves have already grown to more than half their size before the true flowers open, and their time of greatest beauty does not come until after the flowers have fallen. The flowers and the floral leaves open and fade before the trees put forth their true leaves, so that they appear in flower like one mass of dazzling white.

The Cornels with showy floral leaves are confined to the New World, the group being represented by the two Flow-

ering Dogwood-trees, one in the east and the other in the west, and by the pretty little herbaceous Bunch-berry, a familiar flower of our northern woods, which it carpets in spring with its large white bracts, and cheers in the late autumn by its large clusters of brilliant scarlet fruit, and by another species resembling this last, and peculiar to Alaska and the far northern parts of the continent. These are all that have come down to us from a very peculiar group of plants which, in earlier times, were more widely scattered over the earth's surface than they are now. For the ancestors of our Flowering Dogwoods occurred in Europe, where, however, their descendants have been unable to obtain a foothold, as well as in America.

As ornamental trees, the Flowering Dogwoods, especially the eastern species, are not easily surpassed. This tree, to which botanists have given the name of *Cornus florida*, is a low, round-headed plant, with spreading branches and a straight, usually slender, trunk. Under favorable conditions it attains sometimes in the south a height of forty feet, with a trunk often a foot or a foot and a half in diameter. The leaves are ample in size, dark, lustrous green on the upper surface, the lower surface covered with pale glaucous bloom. They turn in autumn to a crimson color, which finds its only equal in brilliancy among American trees in those of the Sour Gum and of the Liquidambar. The effects of the color of the tree at this time of the year are heightened by the contrast between the darker hues of the upper surface with the paler shades of the lower. The fruit is an oval scarlet drupe half an inch long, borne in dense spherical heads. It ripens in the late autumn, and then adds much to the beauty of the trees when birds permit it to escape them. The claims, therefore, of the Flowering Dogwood as an ornamental tree are its hardiness, its size and habit, the beauty and durability of its inflorescence, its handsome foliage and fruit and the brilliancy of its autumn foliage. It grows from southern New England and Minnesota to Florida and eastern Texas, reappearing on the mountains of north-eastern Mexico. This tree is not common at the north, and east of the Hudson River it never reaches any great size. In the middle states, however, and in the south and south-western part of the region which it occupies, it is one of the most common inhabitants of the forests of deciduous-leaved trees, affording the most conspicuous feature in the landscape, and lighting up the borders of forests and fields with masses of dazzling white.

This little tree produces wood which is not exceeded in strength and in the toughness and closeness of its grain by that of many other American trees. It is valued in turnery, for the hubs of small wheels, for the bearings of machinery, and even for wood-engraving. The bitter properties of the bark make it useful as a tonic and give it a place in the materia medica.

The appearance of this tree when in flower is shown in our illustration on page 431. It represents a fine specimen growing in the country place of Mr. A. L. Barber, at Grimes' Hill, Staten Island, and is from a photograph by J. Loeffler, Tompkinsville, New York.

The Pacific Coast Flowering Dogwood, the *Cornus Nuttallii* of botanists, is in some respects a finer tree than its better known Atlantic relative. It grows taller, and it is not unusual to find individuals among the great Fir-trees near the shores of Puget Sound, a region remarkable for its great trees, sixty feet or more in height. The flower-bracts are nearly twice as large, and therefore more conspicuous. The leaves, however, do not assume the brilliant autumn tints of those of the eastern tree, and its tall, slender mode of growth makes it less desirable as a cultivated plant. Apparently the Pacific Coast Dogwood is not an easy plant to cultivate outside the region where it grows naturally. It was first introduced into gardens many years ago, but we cannot remember to have ever seen a plant of any size in any garden, and all recent attempts to cultivate it have proved unsuccessful. Other plants of the same region are, however, perfectly at home

in the gardens of Europe, and a few of them, like the Vine Maple, do fairly well in those of this country. It is possible to hope, therefore, that when the secret of the successful method of cultivating this western Dogwood has been discovered, an ornamental tree of the first class will be given to our plantations.

This species grows from British Columbia to the mountains of southern California. It attains its greatest size in western Oregon and Washington Territory, and the traveler through the great Fir-forests of that region at the time of year when the Dogwoods are in flower will never forget the impression upon his imagination which their appearance creates.

The Treatment of Trees in Drought.

WHENEVER there is a severe drought in New England the newspapers tell us that the great Elms in various towns have died, and that the street officers are about to cut them down. But it takes more than one summer's drought to kill an Elm that was growing vigorously when the dry weather began. Drought often kills trees the first summer after they are planted, and when they are dead beyond doubt they might as well be cut down or dug up to make room for others. But if a tree that has been for some years firmly rooted is so afflicted and starved by drought as to lose all its leaves in midsummer, that is not a sufficient reason for cutting it down. It may die the following year if nothing is done for its relief, but the rains of the coming winter and spring would probably revive it. A tree which is supposed to be killed by drought should never be cut down before the opening of the summer of the next year.

But a tree which gives signs of perishing by drought ought to receive sympathy and assistance. The wilting, turning yellow and falling of the leaves are signals of distress. Usually the tree is starving. It cannot assimilate and appropriate solid substances, and as there is no water to dissolve its food it can neither eat nor drink, and has no means of sustaining its life. But a tree of vigorous constitution, growing in its native soil, will endure a long and severe fast. Of course it will not grow while it is starved, and in time its constitution will be impaired, its strength will give way and it will die. But it should not be cut down because it is having a hard trial.

The trees that are soonest injured by drought have in most cases nearly exhausted the soil in which they stand. The treatment required is not merely a supply of water, but an improvement of the soil. Grass and weeds should be removed from the ground about the tree as far as the roots extend, and either rich loam or manure of a suitable kind should be copiously applied and partially incorporated with the surface stratum. If enough water is then given it from time to time to dissolve the new supply of food, the tree is likely not only to live, but to grow much more vigorously than before. Great numbers of trees in our towns grow very slowly, become enfeebled and perish at last, not on account of drought alone, but because of exhaustion of the soil and an inadequate food supply. The people of a town ought not to remain comfortably indifferent while the noble trees which embower their daily walks are starving to death. They should take measures for their relief. Very often it would be better not to plant so many trees unless they are taken care of afterward. In many instances, Arbor-Day planting is the ceremonious murder of beautiful young trees, which are put into the ground with songs and orations, and are, apparently, not thought of afterward.

The groups of large trees will usually be accompanied by shrubs to connect them with the lawn: Rhododendrons and other pendent evergreens are very useful for such purpose, when the turf being carried under them leaves no cutting line of border. Shrubs should not be accompanied in the same bed by such flowers as require digging, the line of border above mentioned destroying that repose and that variety of form which ought to characterize the former.—*W. S. Gilpin's "Practical Hints," London, 1832.*

California Forests and Irrigation.

NO other part of the United States has so much at stake in any proposed system of irrigation as California. Farther north there is more rainfall, and farther south and east there has been little done as yet, in horticulture, and while the mining and pastoral communities in those regions have much to gain from almost any attempt at irrigation, they have less to lose from hasty experiments or reckless legislation. As the traveler comes westward from the valleys and plains of Colorado and Utah, the gardens of the Rockies, he sees in Nevada, as in much of New Mexico and Arizona, a land indeed arid, but nevertheless a land that can wait if need be. Few wheat-fields and vegetable farms and no great commercial orchards and vineyards are yet established in this vast territory. It is chiefly the great American speculator who urges the immediate expenditure of millions of dollars to restore fertility to this Sahara of the continent. There is no need of haste; let the work be done as increasing population presses hard on its food supply.

But California has a different claim. She has developed by a marvelous chain of circumstances a group of great industries that depend not partly nor temporarily, but absolutely and forever upon two things: (1) the permanence of the remaining forests upon her mountains and (2) the adoption of the most perfect system of irrigation under the best laws that human skill and experience can devise. Unlike Nevada, Arizona, New Mexico, Texas, Montana, Idaho and Wyoming, this great commonwealth has already established orchards and vineyards, which represent potentially the most important horticultural investment in the world, and every new fire in the Sierra Pines, every new logging camp in the Redwoods, every day's delay in the passage of laws to withdraw from entry all the timber-lands that yet remain, is as much a blow at vine and tree in the valleys as if the axe were actually laid at their roots.

While the thirteen American colonies were fighting King George, the Spanish settlers of California were planting vines and Olive trees, avenues of Pear, Fig and Orange, and establishing at more than a hundred mission villages and "ranchos" plantations that a century later were to become gardens of beauty and broaden into thousands of acres of fruit trees and vines. With few exceptions these old Spanish homesteads are the centres of the famous horticultural districts of the present time. Spain, Italy, Portugal and Mexico gave of their best to the gardens of the past, and the course of the ultimate growth of California was decided by that gift. The "gold rush" and the placer mining episode were merely a summer or two of camping in the foot-hills and splashing in the bright Californian rivers. When "the boys" came back from the mountains, there were the mission wheat-fields to bid them break the broad Sacramento plains; there were the mission vines and orchards to show them the real work of the future. Then they planted 15,000,000 fruit-trees and 15,000,000 grape vines. That, at least, is what they have to-day, after numberless experiments, and having utilized the greater part of the lands that under existing conditions are perfectly well adapted to horticulture, they begin to look abroad over their own wheat fields and pastures, which have the soil and climate required, but need security of another sort. Some of the orchards and vineyards are on "sand plains," once covered with *Artemisia* and *Cactus*, but reclaimed by irrigation. Most of them, however, have merely taken the place of Willow "bottoms," Oak-forests and miles of tangled mountain shrubs, and the actual leaf-surface is hardly greater in any of the valleys than it was before the orchards were planted.

Meanwhile the forests have been cleared at a rate which has never been surpassed in any community of equal size. Wood is almost the only building material in use in California. There are a few buildings of brick and stone, but these are but the exceptions to the rule. Then, too, the great mining operations have used up the forests with frightful speed. There are miles of flumes, miles of timbering and flooring, and "blocks" in tailing races, all cut from the best part of the trunks, with the rest left to perish. The Comstock mines have used up timber enough to build a city. Every smelter's furnace clears off acre after acre, usually taking only "fine milling lumber." The building of the stamp mills requires an amount of timber that astonishes the visitor. When a miner takes up a claim he first assures himself that water and wood are in the vicinity, without which it cannot be worked. No one who only knows the ordinary wastage of forests in other regions can have any adequate conception of the enormous and increasing requirement of the miner's pursuit. If the forests were withdrawn from sale, put under capable control,

and the "timber crop" sold in the open market, the miners would soon discover that they could get along with much less and the insane waste now going on would be prevented.

I have seen the bottom of cañons in the mining region literally crowded for miles with the trunks of Pines from each of which a few "flume blocks" had been sawed, and the rest discarded, though sound to the centre. I have seen mining reservoirs made in cañons, and many acres of stately Pines and Spruces left to perish as the water rose behind the dam. No one thought that it made any difference; the supply was called "inexhaustible." About twelve years ago, while a traveling correspondent of the San Francisco *Bulletin*, I rode over the mining districts of Nevada, Placer and El Dorado Counties, a region covering an area of more than 3,000 square miles. Near one of the little mining camps I made the acquaintance of a pioneer named Rayburn, who had a saw-mill, and obtained most of his timber from Government land. One night when I sat in his cabin he asked me if I "had ever seen a Pitch-Pine-tree on fire?" "Now, that is one on the point of the ridge," he said, pointing to a stately specimen, "and I'll send Jim up to touch it off for you." Like a recent writer on forests and irrigation in one of the leading magazines, he had no conception of the Chinese fire-cracker folly of the idea of touching a match to a great Pine merely to see it blaze and fall, and it took half an hour to persuade him out of the notion of his pyrotechnic display.

The causes and extent of the forest-fires of the Pacific coast have often been discussed, but I cannot refrain from giving a bit of evidence from Professor Joseph Le Conte. In a recent conversation he referred to "one of the saddest sights" he ever beheld. It was a fire-killed forest in Oregon. "For thirty miles," he said, "I rode across a belt of timber. The trees had been magnificent Pines, few of them less than 250 feet in height. Fire had destroyed every vestige of vegetation, and in places the soil was burned out in great pits and hollows." The traveler in the Californian mountains will often come upon such fire-swept districts, where miles upon miles of forests that belong to the whole American people stand in utter ruin.

The lesson that Californians are strangely slow to learn is that the prosperity of the orchard-planted valleys depends upon the maintenance of the forest-reserves. The shortage of the Delaware peach crop of 1890 is said to have added a million dollars to the value of the California peach crop. But the limits of the possible extension of the peach industry are fixed by the condition of the high Sierras and of the upper ridges of the Coast Range. If California keeps the forests as the orchards of the mountains, gathering the annual timber crop as she gathers her annual fruitage in the valleys, then orchard belt and Pine belt will meet, and the whole state blossom, and every acre of barren waste be reclaimed at last.

Professor George Davidson, one of the most careful of observers, made a report, now almost forgotten, on the irrigation of the two great valleys, the San Joaquin and the Sacramento. This report, sent to Washington in 1876, still remains the most complete and practical study of the subject, but its suggestions have never received attention. The region under consideration, including valley and low foot-hills, covers 12,000,000 acres. Professor Davidson shows that the average rainfall in the mountains is sufficient to irrigate every tillable acre of this great district, and that the engineering problems involved are not difficult. He tabulates the catchment basins of all the streams on either side of the valleys, and shows that on the maintenance of the great forests the success of the entire system depends. First, he says, the waters must be controlled, placed under a general system of law and be irrevocably bound to the lands they irrigate. Secondly, the forest must be maintained in a systematic manner, so as to avoid waste. Thirdly, the development of a complete irrigation system must go hand in hand with a drainage system to reclaim the swamp and tule lands and carry off the surplus water from the plains. The Davidson Report, which makes a large volume of several hundred pages, illustrates the possibilities of scientific irrigation in California by the best examples of similar work in other countries, but its chief value is in the clear presentation of the necessity of utilizing the water of the Sierra if horticulture is to reach its full development in the great valley.

An ideal California is yet possible, but a few more years of neglect will forever destroy that ideal. California should be a state with one-third of its surface one vast garden and orchard, one-third occupied by great and permanent forests, yielding a revenue almost as large as that of the lowlands, and one-third snow peaks, wild Alps of rocks, high, open pastures and level tule islands reclaimed and changed into such Grass-fields as those of Holland. Everywhere there should be

sufficient water, but nowhere torrents nor uncontrolled floods. On every terraced hill should flourish the Olive and Carob, the Vine and Orange, and the miners should toil in their camps among stately Pines.

Niles, Cal.

Charles H. Shinn.

Earliness from Unripe Seed.

DR. STURTEVANT'S remarks on page 355, alluding to experiments at Geneva in growing Tomatoes from unripe seed, invite a reply, which I have delayed offering for a few days, until the different strains now growing in the garden of the Wisconsin Agricultural Experiment Station should have ripened their first fruits. A brief history of the case is this: Seed of the Cook's Favorite Tomato has been saved from very immature fruits through five seasons, the fruits being selected in every case from the plants grown from immature seed. The fruits from which the seed was saved had not attained full size, and exhibited none of the indications of ripeness.

The present season, the first fruit from the immature seed ripened on August 8th, while that from plants grown every year from thoroughly mature seed ripened August 14th, showing a gain in this case of six days in favor of the immature seed. The dates of maturity of the two selections, that is, from the immature seed and from the ripe seed, in our Geneva plantings are not at hand, but it is my impression that in some instances the gain has been greater than this. In a slightly different strain which was originated in 1889, by selecting thoroughly ripened fruits from the plants grown for three seasons from immature fruits, the first fruit ripened this season ten days in advance of that from the seed grown continuously from ripe fruit.

This experiment, including certain branches not here mentioned, has proved most interesting and instructive; and it is our intention to publish the results in detail when carried a little farther. I will only add here that the increase in earliness is accompanied by a marked decrease in the vigor of the plant and in the size, firmness and keeping quality of the fruit.

University of Wisconsin, Madison.

E. S. Goff.

The Cactus in Garden Art.

The Cactus is a curiosity, one of the wonders of the vegetable kingdom. It is unusual, and therefore always bold and striking. For this reason it is a favorite with many as an object of ornamentation in lawns, and the species are often used in composition for landscape effect. In fact, so common is this use of Cactuses that we may take them to represent a type of ornamentation which is characterized by obtrusiveness and uncommonness. This is almost universally the form adopted by those who have a shallow love of Nature. It indicates that the designer is less in sympathy with his surroundings than with other regions, and that his desires are to be satisfied only by something which appeals at once to the eye as peculiar. Such types of gardens are common. One frequently sees glaring curves, angular banks, balanced figures, piles of stones, curiosities and abundance of abnormal and unusual trees and plants, but he rarely finds a picture painted in a landscape with the same taste that the artist defines and composes on his canvas. And even when we do find a garden created in the love and appreciation of Nature we are too apt to pass it by as tame or commonplace.

It is apparent that if Cactuses are to be used in landscape work, they must be treated wholly as accessories are treated, in the same manner as we treat a rockery or anything which is out of keeping with the general spirit of the scene. They should be inconspicuous, unless near a greenhouse or in restricted areas devoted to rarities and curiosities. In this climate they should never form an integral part of the landscape, for they never combine well with greensward and trees.

But we are not to be understood as discouraging the cultivation of Cactuses. We are only protesting against the grossness of fashion and taste which is too often confounded with landscape-gardening. Fashion often springs from an inharmonious with nature, while landscape-gardening is always inspired by the genius of contiguous landscapes. As greenhouse plants, Cactuses possess many merits, and are eminently worth much more general cultivation. They possess, in a remarkable degree, curiousness and beauty, and they present an almost endless variety of forms and peculiarities. . . . The peculiarities of shape and form, combined with the great beauty of their flowers, are the very features which tend to make them common favorites for lawn decoration. But everything must have its place, and it should be borne in mind that Cactuses are valuable as Cactuses, not as elements in the landscapes of our climates.—*The American Garden.*

New or Little Known Plants.

Prunus Allegheniensis.

MANY years ago, during a visit to the late J. Roberts Lowrie, Esq., of Warriorsmark, Huntingdon County, Pennsylvania, he called my attention to a strange Plum growing along a fence-row in his neighborhood, and supposed by him to have been sown there by birds. Specimens of this Plum, which may have been in flower only, and hence hard to distinguish, were sent to Dr. Gray, who returned the name *Prunus insititia*. Thus the matter rested until, on further investigation, it proved to be not an introduced foreigner, but a new species, and was published in the March number of the *Botanical Gazette* for 1877. Recent study of the plant in its native haunts and in cultivation enables me to give the following amended description:

A shrub with straggling branches, three to five feet high, sometimes over twelve feet, and in port and form a small tree, seldom thorny; leaves obovate elliptical, acuminate, finely and sharply serrate; petioles three lines long, pubescent, as well as the midrib and bases of the veins on the lower side of the blade; flowers in umbel-like clusters of two to five, from terminal and lateral buds, coetaneous with the leaves; pedicels filiform, hairy under a lens, or smooth, a fourth to half an inch long; calyx two to three lines long, minutely pubescent, the tube obconical, the teeth oblong-ovate, obtuse and shorter than the tube; petals round-obovate, three lines long; stamens very slender, some of them as long as, or longer than, the petals; drupe globose, about four lines in diameter, dark purple, covered with a bloom; stone obliquely obovoid, with a blunt point, the one suture capped by a strong ridge, rounded and marked lengthwise by a shallow groove, the other flattish and furrowed by a deeper groove.

The species, as far as yet traced, has a limited range, occupying a territory for the most part of the wildest character. Of frequent occurrence in the north-western corner of Huntingdon County, it extends from the limestone bluffs on the Little Juniata, near Birmingham (Miss N. J. Davis), over the so-called "barrens" to Centre County on the north and Spruce Creek on the east, and thence westward over Bald Eagle Ridge and Bald Eagle Valley and the Allegheny Mountain to Clearfield County and Boon's Mountain, Elk County (McMinn).

Even as a low shrub it bears a great abundance of fruit, which seems to be exempt from the attacks of insects. These little plums have a pleasant acid taste, and are known as "sloes" by the inhabitants of the region, and sometimes used by them for making pies and preserves.

In the drawing made by Mr. C. E. Faxon to illustrate this plant (see page 429), the flowering branch was taken from a plant that bloomed this year in the Arnold Arboretum, and the branch with mature leaves and fruit was furnished by the writer.

Easton, Pa.

Thomas C. Porter.

Lilium Henryi.

AMONG the hosts of new and interesting plants collected in western China by Dr. Henry were a series of specimens of Lilies from Ichang, comprising *L. giganteum*, *L. tigrinum*, *L. longiflorum*, *L. Brownii*, and a new one which Mr. Baker named in compliment to its discoverer. Bulbs of this new species were also collected and forwarded to Kew through Mr. Ford of the Hong-Kong Botanic Gardens, and one of these is now in flower at Kew. In habit it is not unlike *L. lancifolium*, but the stem is thinner, three feet high, the leaves from one to two inches apart, each six inches long by an inch in width, the texture as in *L. lancifolium*. Dried specimens show an inflorescence a foot in width, consisting of a loose corymb of sometimes eight flowers, but the Kew plant produced only two buds, and one of these fell off before it developed. The individual flower is three inches across, the segments recurved as in *L. lancifolium*, two and a half inches long and an inch wide, channeled, very distinctly papillose on the lower part, colored bright orange-yellow with a few small spots of purple. The stamens are as long as the perianth segments, green, with yellow anthers.

Horticulturally, this Lily should prove at least as useful as *L. tigrinum* and *L. lancifolium*. The smallness of the inflorescence on the Kew plant is accounted for by the fact that the bulbs when received were small and partly decayed. Next year the plants should be much better.

Kew.

W.

New Orchids.

CYPRIPEDIUM ELINOR, N. E. Br.—A hybrid raised in the collection of Mr. Drewett, of Mill-on-Tyne, between *C. superbians* and *C. × selligerum majus*, the latter being the seed-parent, to which it bears a considerable resemblance.—*Gardeners' Chronicle*, July 12th, p. 38.

CYPRIPEDIUM YOUNGIANUM.—A hybrid raised by Messrs. F. Sander & Co., of St. Albans, between *C. superbians* and *C. Rabeleni*, the latter being the pollen parent. It is a delicately colored flower and tolerably intermediate in character. It received an award of merit from the Royal Horticultural Society on July 8th last.—*Gardeners' Chronicle*, July 12th, p. 51; July 19th, p. 81.

MASDEVALLIA SCHRODERIANA.—Exhibited by Baron Schröder at a meeting of the Royal Horticultural Society on July 8th last, when it was awarded a first-class Certificate. The flowers are described as rich crimson, the lower part, however, being white. It is said to be allied to *M. Rothschildiana*, a species also unknown to me.—*Gardeners' Chronicle*, July 12th, p. 51; July 19th, p. 81.

ZYGOPETALUM CRINITO-MAXILLARE.—A hybrid raised in the collection of Lord Rothschild, of Tring. The lip is described as violet, with a few white areas, the sepals and petals green, with bold brown spots. It was exhibited at a meeting of the Royal Horticultural Society on July 8th last, when it received an award of merit.—*Gardeners' Chronicle*, July 12th, p. 51.

CYPRIPEDIUM HOOKERÆ, var. VOLONTEANUM, Rolfe.—A very pretty Bornean introduction, which has appeared both with Messrs. F. Sander & Co., of St. Albans, and Messrs. Hugh Low & Co., of Clapton. The lip is a little constricted below the mouth, the staminode unnotched, and the broad petals much spotted on the basal half. It received an award of merit from the Royal Horticultural Society on May 28th last, when it was exhibited by Messrs. Sander as *C. Volanteum*, though, botanically, I do not think it is more than a variety of *C. Hookeræ*.—*Gardeners' Chronicle*, July 19th, p. 66; May 31st, pp. 684, 687.

ÆRIDES J'ANSONI, Rolfe.—A Burmese introduction of Messrs. Hugh Low & Co., intermediate in character between *A. odoratum* and *A. expansum*, and supposed to be a natural hybrid between them.—*Gardeners' Chronicle*, July 19th, p. 66.

MAXILLARIA LONGISEPALA, Rolfe.—A graceful and pretty species, sent from Venezuela by Monsieur Bungeoth to Messrs. Linden, L'Horticulture Internationale, Brussels. The flowers are very large, the sepals and petals light purple-brown, faintly striated with a darker shade, the lip much shorter and greener. A plate will appear in the next issue of *Lindenia*.—*Gardeners' Chronicle*, July 26th, p. 94.

MASDEVALLIA ROLFEANA.—A very pretty little species, allied to *M. demissa*, but with much larger flowers. These are deep crimson-brown, with yellow tails. It was exhibited by Messrs. F. Sander & Co., of St. Albans, at a meeting of the Royal Horticultural Society on July 26th last, when it received an award of merit.—*Gardeners' Chronicle*, July 26th, p. 106.

Foreign Correspondence.

London Letter.

NEW NEPENTHES.—Conspicuous amongst the new plants of last year was *N. Burkei*, introduced by the Messrs. Veitch, from Borneo, through their collector, Burke. It is a remarkable species in the absence of the vertical-toothed wings, which form a conspicuous feature in the pitchers of *Nepenthes* generally, and also in the form of the margin of the pitcher; moreover, it is a free grower, pitchers well and is very brightly colored. Messrs. Veitch have now obtained first-class certificates for two varieties of *N. Burkei*, both of them very distinct from the type, though still possessing its main features. The variety named *Prolifica* is certain to become a popular garden plant from its compact habit and profuse production of pitchers. The leaves are only about six inches long, by about an inch in width, whilst the pitchers are five inches long, and colored pale Apricot-yellow, with dark crimson blotches. The plant certificated was only eight inches high, yet it bore seven-teen fully developed pitchers. The other variety certificated is named *Excellens*. In habit this is more like the type, differing

from it mainly in having pitchers more inflated at the base and much more highly colored. All three deserve to rank amongst the most ornamental of *Nepenthes*. A word of praise may be set down here concerning *N. Dicksoniana*, a hybrid raised at Edinburgh, and distributed by Messrs. Veitch two years ago. It is by far the noblest of that group of *Nepenthes* represented in *N. Rafflesiana*—small plants, producing enormous, well colored pitchers, whilst the constitution of the plant is as vigorous as that of the best of the genus. In my opinion, this and *N. Mastersiana* are the two best hybrid *Nepenthes* hitherto raised.

NEW SARRACENIAS.—There are now a considerable number of hybrid *Sarracenias*, which have mostly been raised in English gardens within the last twenty years. The first to succeed in this direction was the late Dr. Moore, the Curator of the Glasnevin Botanic Gardens, who raised *N. Moorei* from

the *Sarracenias* being a yard through and as much in height. Being grown in a sunny, unshaded house, the pitchers assume most vivid colors. To recommend the species of *Sarracenias* for American gardens would be like sending coals to Newcastle, but the English-raised hybrids may not be so well known in America. Mr. Bull and Mr. Williams are the principal trade growers of these plants here.

DRACÆNA MISS GLENDENNING.—There are hundreds of varieties of colored *Dracænas*, all the progeny of *D. terminalis*, which, by the way, is green in the wild form, the color and endless variety being the outcome of high cultivation and crossing. For ordinary purposes there are few that equal *D. terminalis* as known in gardens, as it stands well, colors freely, is elegant in habit and easy to grow. Messrs. B. S. Williams & Son obtained a certificate for one named as above, and which

Fig. 53.—*Prunus Allegheniensis*.—See page 428.

N. flava, crossed with *N. Drummondii*. This was in 1872. Various combinations of species have been obtained since then, some of them beautiful additions to the genus. The latest hybrids were three which were raised in a garden at Lincoln from *N. Drummondii alba* and *N. Chelsoni*, itself of hybrid origin. These were exhibited recently at a meeting of the Royal Horticultural Society, by whom a certificate was awarded to the best of the three, which was named *S. Claytoni*. The pitchers in this were about eighteen inches high, slender, in shape similar to those of *S. Drummondii*, whilst their color was rich crimson, shaded with purple and reticulated with very dark veins. This is certainly the best colored *Sarracenia* hitherto obtained. The other two exhibited were from the same parents, but different in the form and colors of the pitchers. A collection of well-grown *Sarracenias* is about as interesting as any foliage plants can be, and almost as much may be said of them as flowering plants. All the best kinds are included in a large collection of insectivorous plants at Kew, some of

was generally voted an exceptionally elegant variety. It has narrow, tapering, arched leaves, deep green, with a broad margin of rich crimson. As a table plant it is certain to become popular.

CLIANTHUS DAMPIERI.—Whether it be due to the grafting or to the exceptional constitution of the variety, it is certain that this plant is at Kew a perfect success in the open air. It is planted in a narrow border of loam and trained against a wall looking south-east. When planted late in June the stem was only three inches high, and yet, in spite of cold, wet weather, it is now a large, well-branched plant, clothed with healthy leaves and bearing numerous clusters of its brilliant colored flowers. Nothing could be more attractive, nor apparently anything much easier to obtain, than this plant as it is now at Kew. Probably the sturdiness of the plant is the result of its being grafted on *C. puniceus*. The variety called German Flag is remarkable in having the segments which form the keel white, with a scarlet margin.

OLEARIA HAASII.—This is probably the most useful of the numerous species of this genus which have so far been introduced from New Zealand and tested in gardens in this country. At least a dozen species could be named as having larger and prettier flowers than this, but they are either too tender or too straggling in habit to obtain a place amongst first rate hardy flowering shrubs. When first introduced *O. Haasti* was cultivated in pots in the greenhouse, and it was only after about a dozen years' trial that its hardiness became generally known. In many of the best gardens in England it is now largely used both as a small specimen plant for the border and in large masses for bold effect. At Kew it is particularly effective in the form of large beds, which are now a mass of white starry flowers. It is also fine as a specimen. The plant is as compact in habit as the common Box, and it bears the knife or shears quite as well as that plant. Grouped with summer-flowering plants, such as *Liliums* and *Gladioli*, it forms a most satisfactory ground or foil. Then it possesses the exceptional quality of remaining a long time in bloom, and of being at its best in the month of August. At Kew there are several plants of it trained against a wall, and these are quite as well flowered as those in the open, and apparently as healthy. In the warmer parts of England it grows apace; I have seen it in south Wales over six feet high and eight feet in diameter. It may be propagated from cuttings with as much ease as Box.

EUCRYPHIA PINNATIFOLIA.—Although one of the handsomest of flowering shrubs or small trees, and notwithstanding its having been in cultivation in England at least ten years, this plant is yet scarcely known in ordinary gardens. In the nursery of Messrs. Veitch at Coombe it is a great attraction at this time of year, being thickly clothed with pure white flowers as large as, and shaped like, those of the St. John's Wort, its near relative. In gardens where this plant will succeed it should be well represented, for it is handsome even when not in flower. A basket of flower-branches was one of the most attractive of the exhibits at the last meeting of our Royal Horticultural Society. A word in respect to the propagation of this plant. It does not strike freely when cuttings of ripened wood are used, but if the young shoots are taken when about half ripe and placed in a little warmth they strike root in a short time.

ABIES TSUGA.—This handsome Japanese species has just obtained a first-class Certificate notwithstanding its having been introduced as far back as 1853 by the late Dr. Siebold and named *Tsuga Sieboldii*. It has the habit and general appearance of the Canadian Hemlock Spruce. It forms a pretty pot specimen as well as being an elegant conifer for small lawns, etc. It is, of course, quite hardy in England. There are good examples of it on the lawns at Kew.

TILIA EUCHLORA.—Some branches of this Lime were lately shown by Messrs. Veitch and obtained a first-class Certificate. It is a tree of striking appearance, having heart-shaped leaves fully seven inches long and wide, the texture leathery and the color a deep glossy green. Messrs. Veitch recommend it as a fine avenue tree, holding its leaves much longer than ordinary Limes. It has been introduced from Japan.

Cultural Department.

Preparing for Easter Flowers.

AT the late Florists' Convention in Boston, Mr. James Dean, of Bay Ridge, New York, read an essay on the Easter flower trade. The extracts which we give below comprise the more strictly cultural portions of this paper:

Three-fourths of all the Easter Lilies are now forced from bulbs of *L. Harrisii*, which is more profitable and flowers more freely than *L. longiflorum*, and the plants are not liable to come blind. They can be forced with safety at a higher temperature than plants of *L. longiflorum*, and if they are removed to a temperature of fifty degrees at night, with air during the day, two weeks before the flowers open, they will be just as firm and will yield nearly twice the number of flowers. Most of the Lily bulbs come from Bermuda in July and August. They are at once potted in a light sandy loam to which has been added about one-third of well-rotted manure. The bulbs are placed about one inch below the surface of the soil, and the pots are then set close together in a frame out-of-doors, treated to a good watering, and covered with a mulch of hay or straw to prevent the soil from drying out rapidly and save watering. They can remain out-of-doors until frost, although a degree or two of frost will not injure them. From the time they are brought into the greenhouse until New Year's, a night temperature of forty to forty-five degrees with plenty of air during

the day is all they require. After New Year's they may be removed to another house or the night temperature may be increased to sixty or sixty-five and even seventy degrees if the weather proves bad and there is little sunshine. The flower buds should be brought well above the foliage six weeks before Easter, so that one standing in the doorway of the greenhouse can plainly see all the buds. Bear constantly in mind that it is much easier to hold the flowers back by shading and giving plenty of air, which hardens and stiffens them and enables them to bear transportation, than it is to hurry them into flower by steaming the pipes and giving them warm water. Under such treatment, Lilies are fit only for the rubbish heap. Before delivery each flower should be covered separately with fine tissue paper, and the buds or unopened flowers should be treated in the same way. In fact, every plant sent out for Easter should be wrapped, for although it takes a great deal of time in the rush of Easter work there will be little complaint of flowers damaged in transportation if this precaution is used.

The Azalea is second in importance on the list of Easter plants. The most of the plants for forcing come from Ghent, reaching here in October, and although packed carefully they do not always arrive in condition to be flowered the same season. They often drop their foliage and flower buds, and then must be grown another year before flowering. The successful Easter grower never depends on his last importation of Azaleas for Easter forcing, but always carries at least one year's stock of plants ahead to meet loss or damage. The Azaleas during the winter months can be kept in a night temperature of forty degrees, with plenty of air during the day, until eight weeks before Easter. If Easter comes in March, fifty-five degrees will answer at night; if Easter comes in April, fifty degrees will suffice. It will be necessary to set some of the late varieties into heat two weeks earlier. Do not stand the plants under the shade of some convenient tree during the summer months and expect them to flower the following winter. Give them the open sunshine, plunged or planted out in a Pansy frame. If the soil is heavy add sand and leaf mould, as the Azalea delights in a light, loose soil. Mulch, but do not use manure, and water and syringe to keep down red spider. Treated thus they will make a good growth and mature their flower buds and give a good crop of flowers when they are wanted. They should be carefully housed before frost to prevent injury to the buds.

The Hydrangea is now pushing the Azalea closely for second place on the list of Easter plants. And certainly a specimen plant of *H. Otaksa*, covered with its immense clusters of bright pink flowers, is worth seeing. These flower-clusters, often measuring over twelve inches in diameter, and of a color that shows equally as well by gas as by daylight, make the plant very ornamental. Thomas Hogg is still a favorite, with its pure white flowers, and will always retain a prominent place among the plants grown for Easter. *Hydrangea rosea* deserves to be grown in all collections, although the flowers are not as large as those of *H. Otaksa*, nor is the plant such a vigorous grower. The color and the freeness with which it produces its flowers will always give it a place as a market variety. A cutting struck in March, planted out before the first of May in a good rich soil and mulched and watered regularly, will by October make a plant fit to go into a seven or eight-inch pot. The plants should not be pinched or topped after the middle of June if they are wanted for Easter forcing. They may be lifted by the 10th of October, potted in good rich soil and placed in a cold frame until New Year's, with abundant air during the day and the frames covered by night to protect them from frost. They are brought into the greenhouse at New Year's, and given a temperature of sixty degrees at night, with air during the day, for three weeks, after which the temperature is increased to sixty-five degrees at night, with little air during the day, until the flowers begin to color. Then more air is gradually given during the day and the temperature reduced at night to give bright color to the flowers and harden the plant so that it can stand out in the air without wilting, as a great many of our city florists have to display their plants in the open air in front of their stores. This rule holds good for all plants that are forced for flowers, especially so with the Hydrangea and the Rose Madame Plantier, both of which, if grown in a warm temperature and exposed without being hardened, will wilt very badly when exposed to cool air. The Hydrangea when in growth requires plenty of water and an occasional watering of liquid manure will be a benefit to the plant.

The Cytisus comes next in importance as an Easter plant. Two kinds are grown. *C. Canariensis* is best suited for decorations when large plants are required; *C. racemosus* is

Fig. 54.—The Flowering Dogwood.—See page 425.

not of such strong growth, and is better used as small plants, kept in shape by trimming, which it stands well. The flowers are a little larger and of a deeper yellow than those of *C. Canariensis*. The plants grow freely from cuttings in a light soil to which has been added some well rotted manure. Shifted as they require they soon make salable plants if not overpotted. They should not be planted in the open ground during summer, as they lift badly, and often lose all their foliage. The plants should be plunged and mulched out-of-doors in summer, and not allowed to get dry. They can be housed the latter part of October, and will require little forcing for Easter. Forty to forty-five degrees at night with plenty of air during the day until the first of February, then fifty degrees at night with less air during the day, is the proper treatment. From the first of February they will need plenty of water, and one or two waterings with weak manure water will be of benefit, especially if the plants are in small pots.

There are other plants besides these four also largely grown, such as Spiræas, Deutzias, Callas, Roses, Rhododendrons and Geraniums; but their cultivation is well understood even by novices. Bulbs, too, are largely grown for Easter. No cultural directions are required here, although a word may be given as to the cultivation of the Lily-of-the-Valley in pots. Place fifteen pips in a five-inch pot twenty-one days before Easter and set them in the dark under the bench in a warm greenhouse for two weeks. At the end of that time they can be placed on a bench with light and air, to give the foliage its natural color and harden its flowers. Such plants make beautiful and appropriate gifts for Easter, and are in great demand.

Ferns of Singular Form.

AMONG the multitude of Ferns there are many of unique form, and having so striking an appearance as to attract the attention even of the casual observer at once. In this list may be mentioned the Stag's Horn Ferns (*Platycerium*) as among the handsomest and most noteworthy of the many good plants introduced from the South Sea Islands and Australia, and including a number of varieties, most of which are very distinct in character, while all are deserving of cultivation. The most impressive of the *Platyceriums* in general appearance is undoubtedly *P. grande*, a noble plant when well grown, and producing, in common with the other members of the genus, two distinct types of foliage, the one being barren and the other fertile and of very different form. The barren fronds are upright and sheath the base of the plant as with a shield, the upper edges of the frond being divided into numerous forks or lobes, and growing to a height of two to three feet, while the fertile fronds are thrown out at a right angle to the others, and are also divided into forked segments, so that altogether the fronds bear a striking resemblance to the antlers of certain deer. As though in keeping with the odd form of the entire plant, the seed-cases or sori are grouped together in a compact mass near the central part of the fertile frond, the seed-bearing portion sometimes being several inches in diameter and bearing some resemblance to a patch of brown Fungus.

Another fine species of more recent introduction than the above is *P. Willinkii*, a native of Java. It is of free growth even in a moderately cool fernery. This plant is not so large as *P. grande*, though the fertile fronds attain three feet in length at times, and are so covered with whitish scales as to present a frosted appearance. The barren fronds of *P. Willinkii* are somewhat similar in shape to those of *P. grande*, but not nearly so large, and seem soon to have accomplished their mission, as they begin to decay soon after their growth is completed.

P. alcorni major is a great improvement on the type, producing much larger and finer fronds, and is an excellent Fern for exhibition purposes, the fronds being deep green in color and presenting a bold and massive appearance. *P. alcorni* still remains, however, a first-rate Fern for baskets, or for rockeries, and it is doubtless the most hardy of all the *Platyceriums*.

P. Stemmaria, *P. Hillii* and *P. biforme* are other representatives of this genus, all of which grow best when suspended on a block of wood or portion of a Tree-Fern stump, the only soil necessary being some rough peat. When grown on this system frequent watering or dipping will be needed, as they dry out quickly in bright weather.

Another family of strange growth is that of the "Bird's Nest Ferns" (*Thamnopteris*), a genus having ample, entire leaves, which reach a length of from three to four feet and are about six inches in width. The leaves are glossy, a bright light

green in color and of strong texture. They are produced in a kind of whorl around the stem, thus leaving the centre of the plant open, and the crown, being more or less covered with brown chaffy scales, gives it somewhat the appearance of a bird's nest without the eggs. The best species of this genus is *Thamnopteris Australasica*, which is the easiest to manage, and, as a native of a temperate climate, it may be grown in a cool house, or even out-doors in summer if it is only placed in a shady location.

The *Menisciums* also may be classed among singular Ferns, especially *M. simplex* and *M. giganteum*, both of these having the barren fronds, simple in form and also much more ornamental than the fertile fronds, the latter being more contracted and not so enduring in quality. *M. simplex* is the smallest of the genus, so far as I am aware, the fronds being simple and the barren ones auricled or eared at the base, and about six inches in length, while the fertile fronds are entire and much smaller, the under surface being almost covered with the fruit-dots or sori. *M. giganteum* is much larger in all its parts than the one just described, though of somewhat similar character, and it will flourish with rather more heat than *M. simplex* can endure. An ordinary compost, such as is generally used for Ferns, will suit this genus, and they require an abundance of water.

Drynaria musafolia is another of the simple-leaved forms that generally attracts attention. It bears fronds somewhat like those of the *Thamnopteris* referred to above, but having the veins more sharply defined and being of a rather peculiar shade of light green. It is an evergreen plant, and was introduced from the Malayan Islands many years ago.

At least one of the so-called Filmy Ferns may be included in our short list of singular forms—namely, *Trichomanes reniforme*, which might be called the Kidney Fern, a very pretty little plant from New Zealand. It has bright green leaves, which are thrown up from a creeping rhizome, and attain a height of three or four inches.

This is not a rapid-growing plant, and requires a very open soil, such as rough peat and sand, with some broken sandstone and charcoal mixed through it.

Our native "Walking Leaf" (*Camptosorus rhizophyllus*), which is found in many localities in the northern states, though not in large quantities, is worth noting. It is also evergreen, and may well find a place in the cold fernery, where its long, narrow leaves and curious habit of reproduction from the apex of the fronds always excite interest.

Holmesburg, Pa.

W. H. Taplin.

Notes on Shrubs.

Buddleia Japonica is an east Asian plant which has been grown and disseminated under the names of *B. curviflora* and *B. Lindleyana*. These names, however, belong to other different species which would probably not be hardy in this latitude. Although *B. Japonica* is interesting in itself, it is not a shrub to be recommended for small gardens, where conspicuous and attractive blossoming is wanted, because the space can be better filled with plants of a more pleasing and ornate character. The ends of the stems of *B. Japonica* are usually more or less killed by the winters here; but this does not affect the blooming of the plant, and at the end of each new shoot a long, close raceme (sometimes nearly a foot in length) of small, tubular, light purple or lilac flowers is thrown out in July and August. The first flowers open at the base of the raceme, and, as but very few open at any one time, they never appear very showy or ornamental. By the time the terminal blossoms expand the seed-pods at the base of the raceme have become large and well developed. The stems of this plant attain a height of from four to six feet, and, when young, are sharply four-angled or winged, and the roughish looking leaves are from four to six inches long and gradually taper to a point. As the heavy racemes of fruit and flowers at the ends of the shoots give the plants a more or less drooping or pendulous appearance, they lend an added interest and variety to the shrubbery of parks or large plantations. The foliage is dense enough to completely cover the stems, and it seems very free from injuries by insects. Seed is freely and abundantly produced and is easily carried some distance by winds, and, under some favorable conditions, it germinates and grows spontaneously.

Incarvillea Olga is a half shrubby or almost herbaceous plant belonging to the Bignonia family. Originally introduced from high elevations in Turkestan, it has, without any protection, withstood the climate and winters of Boston and shown no injury. *I. Olga* annually produces new shoots from the ground, which become two or three feet in height. These stems are smooth, more or less branched and well covered

with light green pinnatifid leaves. The plants slowly spread from the roots and eventually form large clumps. In this latitude, however, the blossoming is very disappointing. The flowers are borne in racemes at the ends of the shoots, but they are usually so few in number and expand in such slow succession that they add little to the beauty of the garden. The pretty rosy pink trumpet-shaped flowers are about an inch and a half in length and nearly an inch and a quarter across the mouth, and are produced in August and September. It is possible that we have not given the plant the best conditions for fine development, because it seems to be valued in some European gardens. If very free-flowering plants should be produced from seed they ought to be perpetuated by division.

This species is the same as the one figured in the *Botanical Magazine* (t. 6539) as *I. Koopmanni*, and under this name it is still advertised in some foreign catalogues.

Arnold Arboretum.

7.

A Few Annuals.

COMET ASTERS.—The first of this distinct strain of China Asters was introduced a few years ago and met with instant appreciation, but more on account of form than coloring, which was white, lined with pink, and this color fading left the white rather turbid. However, the form was very distinct; the flat reflexed petals with blunt points, arranged rather informally, resembling very much some Japanese reflexed Chrysanthemums. Two or three years since a variety "Rose" followed, which is a great gain and one of the most pleasing of China Asters. The form is like the type, and the color is a beautiful, light, clear pink. This year we have the "Blue" Comet, which, as may be supposed, proves to be a purple, but of a very pleasing, clear light shade—a first rate variety. Both the Rose and Blue Comet Asters can be recommended for addition to the choicest collections.

CHINA ASTER PRIDE OF THE MARKET, a novelty of the season, is interesting for its precocious bloom, as it came into flower about a fortnight before the general collection sown at the same time. It is a reflexed variety, with fair-sized flowers of various colors. The stems are unusually long, and it should be a good strain for the florists. For the garden the growth is straggling, and the plant requires rather more tying up than many would be prepared to give it. However, if early flowers are wanted, this strain is well worth growing.

SWEET ALYSSUM LITTLE GEM.—This strain is a good example of what may be secured by careful seed selection. The entire lot of seedlings is dwarf and compact, without any of the legginess or weediness usual in the ordinary variety. The bloom is white and free as in the type. It is an excellent edging plant, being always in flower, and not outgrowing its bounds.

SALVIA COCCINEA, with its variety *Lactea*, are two beautiful Sages, the former a clear, deep scarlet, the latter pure white. They come true from seed; the plants are some two feet tall, much branched, with flowers borne in long spikes, and though not lasting very well when cut, are useful in bouquet making. To many this variety may prove a welcome change from *S. splendens*, which, while it is one of the most valuable and easiest grown of showy plants, is somewhat tiresome from its commonness.

CHRYSANTHEMUM MULTICAULE.—The introducer of this plant this spring frankly stated that it had been known for many years as "a botanical curiosity," and it would seem that in a botanical collection is its true place. The plants are annual and come into bloom early. It is dwarf growing, with prostrate glaucous foliage. Its flowers are single, yellow, small—an inch across—and plentiful, but only open in bright weather and in the middle of the day, so that its value for garden purposes is very slight, as we have so many better yellow Composites.

Growing Pears.

THE fact that Pear culture is no longer seriously hindered by blight makes a few hints timely as to method of planting and culture. I have for many years grown Pears headed low toward the ground. To secure such I have sometimes negotiated beforehand with nurserymen to prevent their being trimmed up in the nursery. I prefer them branched out at three feet from the soil. The reasons are obvious. (1) They come to bearing as soon as dwarfs, thus saving three to five years before getting a crop. (2) For picking there is great advantage. You can gather the fruit for several years with a step-ladder. (3) All fallen fruit lies comparatively uninjured.

(4) In case of drought the limbs shade the soil and equalize temperature. It must be borne in mind that more damage to fruit occurs from severe changes of temperature than from extreme cold. (5) You are able to trim the trees as they should be without much trouble. Pear-trees should, for the first five or six years, be gone over twice a year. In midsummer cut out all superfluous shoots and suckers, and in November head back the new growth one-third.

I also have for many years grown Pear-trees as Dr. Meehan first suggested, "in grass." By that is not meant that the trees stand in sod, but that instead of being cultivated with the plow they be cultivated with the fork. Let the trees be well mulched with coarse manure or ashes of anthracite coal mixed with wood ashes. Turn this over and cleanse it of weeds once a year and thoroughly aerate it. It should be renewed once in two years. The principle is to keep the feet warm while the head is kept cool. The circle forked over should be larger in diameter each year until it is eight or ten feet across. I use weeds for mulch if other material is scarce. Sawdust is good, especially after being run through the stable for bedding.

No manure whatever should be used in planting a Pear-tree, but a top dressing of coarse manure is often needed. Some varieties require more food than others. The Seckel is a good eater and digests well. The Anjou is another. But the rule is, not to force or stimulate a Pear-tree or a Cherry-tree. But no fruit suffers worse from neglect. Choked by sod the Pear fails to bear any fruit of marketable value.

The Pear-tree is hardier than the Apple and more easily grown. Its culture is never overdone. We could find market for a hundred times the present amount grown—only we must plant with regard to seasonableness. There is a pear glut some years during September. Pears that keep long, like the Anjou, Louise, Bosc and Clairgeau, are marketable from November 1st until New Year's, and always find ready sale. All in all our grandest market as well as table pear is Anjou. It is an ideal fruit. I pick it in early October and have it till Christmas. Another Pear that I like well is Gray Doyenne.

Clinton, N. Y.

E. P. Powell.

Correspondence.

Forests and Scenery in New Hampshire.

To the Editor of GARDEN AND FOREST:

Sir.—I have recently examined portions of the White Mountain region of New Hampshire, seeing as much as possible of the scenery around Fabyan's, Crawford's, the Glen and Profile Houses and about Bethlehem. I went up Mount Washington by the stage-road from the Glen House, and came down by the railroad. I drove through the White Mountain Notch from Crawford's and went out the whole length of the Zealand Valley Lumber Railroad on a gravel train. From Fabyan's and in other places one sees on the mountain-sides extensive tracts which have been burned over, where the dead, unsightly tree-trunks destroy all the value of the scenery for the present. The sky-line, which in all fine landscapes appeals strongly to the imagination, with its suggestions of infinite distance beckoning to fairer scenes beyond the utmost range of vision, is here utterly vulgarized and degraded by these straggling ranks of decaying stumps. While these repellent objects mar the scenery it will yield no delight to visitors who seek the solace and peace of Nature among these mountains. But in a few years the dead trees will have fallen and disappeared. The slopes are already green, as they are growing up with Bush Cherry and other shrubs, which, though worthless for timber, will yet clothe the hills until the burning is repeated.

If we look at it from a few miles away, the forest still appears unbroken over a large proportion of the White Mountain region. But when we go into the woods we find a great deal of cutting, and there is much alarm among the hotel proprietors and their guests on account of the vigor with which the lumbermen are extending their operations in the vicinity of the great mountain houses. All tourists will remember the beautiful drive through the White Mountain Notch from Crawford's, shaded and embosomed under a bower of greenery, mile after mile, all the way. To what multitudes of people the coolness of these woods, and the murmurous music of their crystal waters, have given rest and delight. Now it is ruined. For a large part of the distance the woods have been cut off. The trunks of the White Birches, which rose through the green leafage like slender shafts of silver, have been cut up into suitable lengths for the market, and the tops of the trees sprawl everywhere over the ground in confusion and entanglement. The sun-glare is hot on

the road, and the air seems entirely changed. The sylvan fragrance and freshness are gone.

Everybody who visits the region ought to go up into the woods the full length of the Zealand Valley Railroad, about ten or twelve miles, taking the cars at Zealand Junction, two miles below Fabyan's. That country belongs to Messrs. J. E. Henry & Sons, lumbermen, and they have built a good standard gauge railroad, on which they bring out their timber. It would be an excellent thing if they could be induced to run excursion trains over it. They cut only down to ten inches, but the Spruces stand so thickly that in many places it is difficult to remove the large timber without destroying nearly all. I think these proprietors do the best they can to prevent the complete destruction of forest-conditions, but they are pretty nearly helpless against fire. A fire in these woods in a dry time can be controlled only by attacking it very soon after it starts, and there is no fire-police or forest-guardianship of any kind, except that of individual land-owners. The fire comes some time, and there is a considerable region along this Zealand Valley Railroad which has been burned until it is completely ruined. The soil has been washed away from the steep slopes, leaving the rocks bare and glittering. All tourists who wait for the cars at Zealand Junction should look across the narrow valley in front of the station, and note the two denuded hills or ledges of rock. Their white desolation shows what is the destiny of most of the White Mountain region if nothing is done to interfere with existing conditions and agencies. The ruin is not coming rapidly, but it is coming surely. More and more of the whole region will be cut off, and afterward burned over, till in time there will be no timber, or shade, or verdure, or springs of water in all the mountain country of northern New Hampshire.

What can be done to avert these threatened calamities? It is not easy to say. But the best way of approaching the matter that seems to be open to us in this state, is the establishment of a Board of Trustees empowered to acquire by gift from individuals or bodies of subscribers, parcels of real estate possessing special natural beauty, and to hold the same, together with funds for the maintenance thereof, free of all taxes, they to be required to open to the public all such lands, on condition that the state shall provide some adequate means for the protection of the forests on them from fire. This is about the plan of the association formed in Massachusetts a few months ago for the preservation of scenery and the care of places of historic interest. Under such an arrangement tracts of special beauty and interest near our great mountain resorts could be gradually acquired and forever preserved from spoliation.

Perhaps in time the state might be brought to help. But the first need is that of some kind of association, composed of the leading hotel men and other public spirited citizens of the state, to provide for some degree and method of co-operation. It is not likely that the state will do anything in the matter unless some of the men most directly interested in the pecuniary value of the scenery of the White Mountain region come together and arrange some method of awakening public interest and enlisting public support for a moderate and reasonable plan for the protection of the mountain forests against fire. The state might fairly be asked to provide and maintain some kind of forest-fire police service in the mountain region where the sparse and scattered population is inadequate for such a task. But all this is my personal suggestion only. It is not official and does not commit the other members of the State Forestry Commission to its support.

Some writers on the subject say the state should condemn and appropriate to public uses the entire "Presidential Range" and other extensive tracts in the mountain region. But nothing of the kind has ever been done in this country, and in this state we have not had even the beginning of the educational work which would be required to prepare the minds of the people for a proceeding of such magnitude. If we could have a few years of such preparatory work we might be able to begin in a small way (and that would be the best way) a course of action which would result in the permanent preservation of the best of our New Hampshire scenery. But I suppose that very few, even of our leading citizens, have as yet begun to consider or inquire by what methods anything in this direction might really be attempted or accomplished. Somebody's time and labor would be necessary, and much talking and conferring, writing and publishing—in short, general agitation and discussion.

If New York establishes a great State Park in the Adirondack region it will greatly stimulate attention to scenery interests in New Hampshire.

Franklin Falls, N. H.

J. B. Harrison.

Wheat and Rye Hybrids.

To the Editor of GARDEN AND FOREST:

Sir.—In connection with Mr. E. S. Carman's experiments in hybridizing and his success in producing a hybrid between Wheat and Rye, as told in the last number of GARDEN AND FOREST, it may be of interest to note that other experiments in the same direction have been attempted. At a meeting of the Botanical Society of Edinburgh, held April 8th, 1875, specimens were shown, and a paper was presented by Mr. Alexander Stephen Wilson on "Wheat and Rye Hybrids," which is printed in vol. xii., p. 186, of the *Transactions* of the Society.

Out of a large number of experiments, begun in July, 1873, on Wheat, Spelt, Rye, Barley and Oats, all of several varieties, only plants from two of the resulting seeds were selected as true hybrids. In the author's words, these were from "Wheat ovules and Rye pollen, and the whole aspect of the culm and ear is intermediate between Rye and Wheat. The elongation of the outer pales into awns midway in length between the blunt termination in Wheat and the longer needle of Rye is the most noticeable feature. The thinness of the culm is characteristic of Rye, and so is the slight villosity below the ear, not so observable now as when green. The glumes, also, are intermediate in size between those of Wheat and Rye.

"All the florets on these spikes fully opened, as if intending fertilization, and on some of the ears they did not close again. But what seem to be the most important facts regarding these hybrids are that the anthers did not open nor discharge any pollen; that the pollen was imperfectly developed and contained very little fovilla; and that the imperfect grains remain in the dried anthers. These facts are a sufficient reason why these hybrids are absolutely barren; not a single kernel having been produced. The anthers did not get blanched as empty anthers do, and instead of falling away as is usual they still remain attached, so that the imperfect pollen may be examined by breaking up an anther in a drop of water. The anthers are of Wheat size. In the ordinary fertilization of a Grass, the pollen grains continue to grow until they rupture the anther; in these hybrids this full growth of the pollen grains has been arrested."

Mr. Carman states that his hybrids are growing more fertile each year they are propagated. The above earlier hybrids would be called failures from a utilitarian point of view, and although Mr. Wilson has several other papers "On the Fertilization of the Cereals" in the *Transactions* of the Edinburgh Society, I am not aware that further attempts in hybridizing Wheat and Rye were ever made by him.

Arnold Arboretum.

J. G. Jack.

A Mysterious Conifer.

To the Editor of GARDEN AND FOREST:

Sir.—I have just visited and examined afresh in the Palace Garden at Potsdam the original specimen of *Abies Eichleri*, planted and named by my late friend Lauche. As this tree, for a long time almost forgotten, has recently been much talked of, and as its right to represent a distinct species has been contested, it may be interesting to glance at its history.

A certain mystery always hung around its origin, the exact locality which furnished the seed from which it sprung being somewhat obscure. All that was known was that it was of Caucasian origin, but this seemed indubitably established. Very recently, however, Herr Beissner and Herr Kenning made a special study of *A. Eichleri*, and according to them it is merely a false species, produced by an accidental change of seeds occurring in the consignment sent from Tiflis to Potsdam. After seriously examining all the facts which they could obtain they conclude that this tree is nothing but *A. Veitchii*, of Japan, under a new name and a Caucasian alibi. No one, it was said, had ever seen *A. Eichleri* in a state of nature. But two or three individuals were known, of which the largest, the true mother-tree and the original of Lauche, is at Potsdam, in the gardens of the State Nursery, which forms part of the royal park of Sans-Souci.

On the other hand, Herr Wilhelm Hans von Herrenhut tells us (in 1889) that the very restricted habitat of the species has just been discovered in the wild and romantic valley of Daba, near Borjon, in the Caucasus Mountains. Now, which of these contradictory statements are we to believe? On the one hand we have the testimony of much respected savants, on the other the judgment of a dendrologist as accomplished as the late Herr Lauche, reinforced by the recent discovery of Herr Hans von Herrenhut.

Dr. Dieck, who is on the point of starting for Asiatic Russia, expects to collect and to observe everywhere he goes,

especially in the Caucasus; and being more conversant than any one else with this vexed question, will, we hope, bring us back its solution.

Lauche received the seeds from Monsieur Radde, of Tiflis, that great explorer of the Caucasus, who is still living within its borders. Only a single seed germinated in 1870 or a little later. The plant which it produced so strongly resembled *A. Nordmanniana* that it was at first considered simply a variety of this; but, prematurely producing cones as early as 1881, the abnormal form could not escape the practiced eye of Lauche—they were much smaller and of a bluish black. Moreover, the silvery color of the under surface of the leaves and the very pronounced glaucescence of the young shoots clearly distinguished this conifer from *A. Nordmanniana*, which it otherwise so much resembles.

The original tree at Potsdam is now eight feet in height, with a considerable spread. No one would call it a beautiful object. Placed in a very confined position between other conifers, all of which surpass it in height and in beauty, it merely forms a large bush of irregular tufted shape, having lost its leader, and is making no haste to repair the loss. Since its first attempt at fructification it has remained sterile, so that the rare specimens to be found elsewhere have all been produced by grafting. The specimen in the Botanic Garden at Berlin has remained a dwarf not more than two feet in height. A much better specimen, and one which promises to develop admirably, stands on the Island of Scharfenberg. Its height is about seven feet, and with its fine, straight terminal shoot and its superb silvery color, it is a most attractive object.

Let us hope that we may soon see clearly through the mystery that enwraps *A. Eichleri*. Certainly the last word has not yet been said with regard to it. Lauche believed that he had good authority for the belief that in its native wilds it reaches a height of 100 feet, usually being clothed with branches down to the ground. Moreover, it seems very improbable that seeds from Japan should have strayed to Tiflis, a city so far from the great commercial routes which unite the extreme Orient to Europe. I may add that the person to whom Lauche dedicated the tree was Herr Eichler, the last Director but one of the Botanic Garden in Berlin, who died only a few years ago.

Berlin.

Carl Bolle.

Tree Peonies.

To the Editor of GARDEN AND FOREST:

Sir.—Having been much interested by the letter from Mr. Watson on the cultivation of Peonies in England, which you recently published, I venture to send a few complementary observations upon Tree Peonies.

These plants generally do very well in all soils where there is not an excess of moisture. A good ordinary agricultural soil (Wheat soil) is what suits them best, the fertilizer used being well pulverized cow manure mixed with leaf-mould. Fresh manures should be avoided as very prejudicial. These magnificent plants, as remarkable for the elegance of their foliage as for the brilliant and varied colors of their immense flowers, are all the more valuable as ornaments of the garden because they bloom at a season when flowers are still rare, long before the blossoming time of Roses. One sometimes hears the complaint that Tree Peonies do not bloom until several years after planting. Most often this results from improper methods of propagation. These shrubs, and especially certain strong-growing varieties, do not lend themselves well to rapid multiplication, and each stock normally yields but a small number of good shoots. Yet many horticulturists pitilessly take all the branches which a mother-stock can furnish in order to graft them, if possible, by single eyes. When for several years plants have suffered mutilation of this sort they produce only very small shoots, still suitable for grafting, but utterly incapable of flowering; and young plants obtained from such degenerate shoots are never vigorous; sometimes they take from seven to eight years to come into bloom, and certain individuals never bloom at all.

To obtain vigorous and floriferous plants enough shoots must each year be left on the mother plant to ensure its producing blossoms, and thus furnishing well developed cions which, for the most part, have already borne flowers. I am absolutely in accord with Mr. Watson when he says that the most vigorous plants will be those grafted on *P. Moutan*. But such grafting being little practiced on account of the almost insurmountable difficulty of getting roots large enough to receive fine grafts, we graft on the root of *P. Sinensis*; but instead of grafting a single eye at least two eyes must be taken (and even more if the eyes are very close together), and so disposed that at least one eye is beneath the surface of the

ground. This eye greatly encourages the formation of roots on the graft, and such plants draw a great part of their nourishment from their own roots. Long experience has proved that Tree Peonies thus obtained are always the most vigorous and the most floriferous; and by this method we have plants of extraordinary vigor which delight all visitors by the abundance of their blossoms.

Chenoucaux, France.

Auguste Dessert.

The Pepo of Peru.

To the Editor of GARDEN AND FOREST:

Sir.—In Feuille's "Peru," p. 735, under *Melongena laurifolia*, *fructu turbinato, variegato*, a fruit is described resembling a melon in appearance and taste, and cultivated in gardens at Lima under the vernacular name of *Pepo*. Dunal, in his *Histoire des Solanum*, identifies it with *Solanum muricatum*, Ait., with *S. scabrum*, Lam., and *S. variegatum*, Fl. Peru, as synonyms, and he adds that it also occurs in the gardens of Teneriffe.

Can any of the readers of GARDEN AND FOREST inform me whether this fruit has ever been tested in American or European culture, and whether it has merit as judged by European palates?

South Framingham, Mass.

Recent Publications.

The True Grasses. By Eduard Hackel. Translated from *Die Natürlichen Pflanzenfamilien* by F. Lamson Scribner and Effie A. Southworth. Pp. 236. Henry Holt & Co., New York, 1890.

This is a most interesting volume and it will be indispensable to every botanist who has a library of any pretensions. It will be found worthy of a place on the shelf beside such works as those of Sachs, De Bary, Strasburger and the *Genera Plantarum* by Bentham and Hooker. No man has a better reputation for thorough insight into the structure and classification of the Grasses than has Mr. Hackel, and the results of his patient study are shown on every page. He has taken advantage of the labors of the best agrostologists who have gone before him, whether it be Robert Brown, George Bentham or General Munro.

Part I. treats of organs of vegetation, minute structure, the ligule, the leaf-blade, leaf-torsion, nervation, inflorescence, the spikelet, the stamens, the pistil, pollination, ovule, fruit, seed, starch, means of distribution, geographical distribution and fossil grasses.

At the outset, the difference between tufted and creeping grasses is explained, the latter only being well suited for making the close, even turf so much admired in lawns and old pastures; the difference between the culm-nodes and sheath-nodes is also noted, the latter usually extending farther down the culm. On the third page we are told that the nodes are not, as is often supposed, for the purpose of giving strength to the culm, but their function consists solely in the erection of culms that have become bent down. The parenchyma of the node is geotropically sensitive, and as soon as the culm is bent over, the cells on the lower side of the node elongate, and thus the action of several nodes will again partially place the lodged grains and grasses in an erect position.

The author refers, with some explanations, to the fact that many blades of grasses are twisted one way or the other; that many, when full grown, are uniformly "bottom side up"; that most leaves have peculiar enlarged cells in the epidermis which are very sensitive to moisture and dry air. These are bulliform cells, and aid leaves in closing or "rolling" in a dry time, as in case of Indian Corn.

Part II. consists of keys of analysis and descriptions of tribes and genera. The reader of the best literature on agriculture, as well as the botanist, will find much of interest in this part of the book, which contains valuable information on the history and economic properties of grasses.

Great care has been used to secure accuracy of translation, and a very complete index gives added value to the book. The impressions of the numerous excellent cuts are well taken, and the publishers' work in general is of the best quality.

W. J. B.

Notes.

The importations of fruit into England increased a little more than a million bushels in 1871 to six and a half millions in 1888.

A statue is to be erected at Prague in honor of the famous plant collector, Benedict Roezl. It will represent him seated and at work studying a plant.

It is reported in the Agricultural Department of the *Florida Times-Union* that experiments in tanning with the Mangrove have proved very successful near Fort Myers.

The *North-western Lumberman* for August 2d publishes a sketch of the life of Mr. B. E. Fernow, Chief of the Forestry Division of the Department of Agriculture, with a portrait.

"At a farm-house in Newchurch-in-Pendle," says the *Gardeners' Chronicle*, "Mushrooms grow in profusion in the various rooms on the ground floor. A gentleman visited the place last Sunday, and he found Mushrooms growing out of the chinks of the floor and also from the walls. He was allowed to take several away, one of which was eight inches across. The Vicar of Newchurch often has a dish from the farm-house." It is interesting, but melancholy, to imagine the bodily condition of the dwellers in such a house, and also the mental condition of a clergyman who can enjoy a dainty originating in such a way.

The mantel decoration by Mr. David Allen, which took the first prize at the late exhibition of the Massachusetts Horticultural Society, was composed throughout of choice plants most tastefully arranged, from the great clusters of White Agapanthus rising above masses of Maidenhair Ferns at the base, to the exquisite Croton at the summit. The hanging sprays of Lapageria, both rose colored and white, exemplified the best use which can be made of these flowers, which keep solid and fresh so long. Beautiful Orchids and Nepenthes, *Cocos Wadeliana*, variegated Alocasias, *Adiantum Farleyense* and *Asparagus plumosus* were the other materials principally used.

Among certain remarkable trees to be found in the neighborhood of Vichy, the *Revue Horticole* notes a Black Poplar (*Populus nigra*) which stands in the park, and is called "the great tree of Vichy." The trunk measures six and a half feet in diameter at three feet above the ground, and more than thirteen feet where the huge branches diverge to form a head eighty-two feet in diameter, which attains a height of nearly ninety feet. The age of the giant is supposed to be not more than eighty years. A number of other Poplars of various sorts which stand near by, with trunks from twenty-seven to forty-three inches in diameter, and from seventy to eighty feet high, with a spread of from sixty to eighty-five feet, are remarkable specimens of rapid development, as they are known to be only twenty-seven years old.

Mr. W. R. Smith, of the Botanic Gardens, Washington, says that foreigners call *Tecoma radicans* and *T. grandiflora* "Humming Bird vines" from the fact that their flowers are constantly visited by these birds. Indeed, in one of Audubon's pictures the humming bird is feeding on the nectar of one of these Trumpet-flowers, while another species of humming bird is given in connection with the other. The flowers of *T. radicans* bloom so late that its pollen is carried by the birds to the flowers of *T. grandiflora*, and out of a large number of seedlings raised from this plant by Mr. Smith every one showed traces of the blood of our native plant. Some fine flowers of *T. grandiflora*, from the Arnold Arboretum, attracted much attention at the recent exhibition of the Massachusetts Horticultural Society in Boston.

The Boston *Transcript* says: "The amount of produce a well-managed garden is capable of yielding is well shown by the following statement recently made by G. W. Hallock & Son concerning their fifty-eight acres of land near Greenpoint, Long Island, during last year: 3,750 bushels of onions and 4,500 bushels of carrots; early cabbages, 5,500 barrels; early potatoes, 2,500 bushels; strawberries, 11,000 quarts; onions from sets, 2,260 bushels; white beans, 160 bushels; carrots, 11,000 bushels; late potatoes, 450 bushels; onions from seed, 3,900 bushels; ears of corn, 2,000 bushels; Brussels sprouts, 500 bushels; potato onion sets, 10 bushels; carrot seed, 40 pounds; onion seed, 100 pounds; Brussels sprout seed, 4 pounds; cabbage seed, 2 pounds; Hungarian grass, 3 tons; cabbage plants to carry over, 250,000."

The famous "Physic Garden" at Chelsea, London, is in danger of destruction. The Society of Apothecaries, who, for more than two centuries, have maintained it, are unwilling longer to bear the expense. In accordance with the terms of the will of Sir Hans Sloane, the ground it occupies must now be offered at the same nominal rent to the Royal Society first, and then to the College of Physicians; and, if they both refuse the charge, it can then be freely disposed of by the present heir of Sir Hans, Lord Cadogan. Once a tract of small money value, it is a desirable building site, owing to the extension of the city and the construction of the Chelsea Embankment on one side and of Battersea Park on the other. But it is to be

hoped, if only for sentimental reasons, that a garden of which Evelyn wrote in the seventeenth century, and which must be constantly quoted whenever the history of the introduction of foreign plants into England is touched upon, may be preserved during many generations to come.

In a recent number of the *Revue Horticole*, Monsieur Delabarrière described the great Rose-garden which he has created in the royal park at Laeken, and which is one of the most remarkable in the world. This *roseraie* is at once a garden to please the eye, and a school for the study of the plants, which already number more than 13,000. It forms a vast circle 430 feet in diameter, where sixteen circular beds are separated by as many pathways bordered by low, ornamental plants of other sorts, the beds being ten feet and the paths one and a half feet wide. In each bed there are three rows of Roses, so arranged with regard to their height and the color of their flowers that the general effect shall be agreeable to the eye. Four carriage-ways run from the circumference of the circle in curving lines to the centre, where they meet in a small open area. The ground slopes a little so that the plants are protected from the north wind, and, being commanded by higher portions of the park, the garden forms a delightful scene even from a distance, whence the beauty of the individual Roses cannot be appreciated.

Last winter there were many complaints of a failure of the crop of Spinach in New Jersey, and from what appeared to be a Fungus disease, and Professor Halsted in a recent bulletin from the experiment station of that state gives some account of his investigation of these diseases. Four species of parasitic Fungi were met with, a mildew, an anthracnose, a leaf blight and a white smut. Of these parasites the Anthracnose (*Colletotrichum Spinaceæ*) and the White Smut (*Entyloma Ellisi*) seem to be little known, and the former is probably the most destructive of all, being very contagious and so rapid in its development that healthy leaves showed newly developed disease-spots in six days after inoculation. Inasmuch as the whole Spinach-plant is prepared for the table it is difficult to apply remedies. Of course it is good practice to burn all affected parts of plants and not allow the refuse of the bed to get to the manure heap, and it would be also a good measure to change the location and soil of the beds, growing other crops in the old place for a few years. Perhaps it would be well if the soil were treated with the mixture of flowers of sulphur and air-slacked lime, and copper sulphate might be used upon the plants when young.

A correspondent of the *Gardeners' Chronicle* says with regard to *Chrysanthemum carinatum* recently exhibited at Chiswick by the Messrs. Hurst: "Some curious facts may be noted as to the form, color and movements of the florets. The outermost series are arranged in two or three rows of strap-shaped female florets. Within these come two or three rows of purple florets, half the length of the yellow ones and intermediate in form as in position between the true ray-florets and those of the disc, less regularly tubular than the one, less irregularly ligular than the other and female. The disc is made up, as usual, of very numerous purple, regularly tubular, hermaphrodite flowers. The fruits are deeply winged in all cases, whence the name, but while those of the two outer series have the two wings unequal in size, the wings of the innermost series of disc-florets are regular or nearly so. But these structural peculiarities are not so conspicuous or so interesting as the movements of the yellow ray-florets. In full sunshine these spread horizontally, so that the purple disc is shown surrounded by a golden aureole. As the sun goes down, down go the yellow florets too; the consequence is that the purple disc alone is visible and the yellow florets are hardly to be seen unless specially looked for. This happens when the flowers are cut and placed in water. We have had some on our study table, and have been interested to see in the morning one flower, in the evening apparently another."

Mr. Henry Bennet, widely known as the producer of seedling Roses, died on the 12th of August, at Shepperton, England. Mr. Bennet was engaged in agriculture during his early years, and in his farm practice he brought into use the same scientific precision and clear perception which he afterward employed in raising Roses. He exercised great care in selecting varieties for crossing, kept accurate records, and used a system in interbreeding which produced such fine varieties as Mrs. John Laing, Her Majesty, Princess Beatrice, Puritan, Captain Hayward and many others. There is little doubt that many other seedlings of his rearing will yet be heard from. Mr. Bennet was justly esteemed for the unassuming frankness of his disposition.

The Army and the Forests.

AT the meeting of the American Forestry Association in Philadelphia last year a resolution was adopted to petition the Congress of the United States to pass an act withdrawing all forest-lands on the public domain from sale until a commission appointed by the President shall have made the necessary examination and reported to Congress what part of these lands should be kept permanently in forest. In accordance with these same resolutions, it was asked that the army should be employed to protect the public forest from spoliation and destruction until the Commission had reported a plan for a permanent system of forest-management. The objection which was offered to this last proposition, that the army was not large enough to perform the duties which such an enactment would impose upon it, has some weight, although we are not likely to secure any legislation in the near future which will give to the country the services of a body of forest-wardens which will approach in numbers the military forces which might be made available for this purpose.

The objection, however, that such an employment is not a proper one for the soldiery of the United States does not seem to be well taken. A conspicuous example in which the army, or rather a minute detachment of it, has served in exactly this capacity is found in the management of the Yellowstone National Park. For some reason Congress failed to make any appropriation for paying the salaries of the Superintendent of the park and his assistants for the year ending June 30th, 1887, and therefore a troop of cavalry under Captain Harris was ordered into the park. This was not a military post, and therefore the captain, who acted as Superintendent, had no right to enforce military law, his sole authority, under a special act, consisting in a power to remove trespassers from the bounds of the park. Nevertheless, the presence of the visible power of the Federal Government, as represented by this little garrison, has proved a more efficient protection to the park than could have been hoped. It is reasonable to suppose that the same moral effect would follow if the forests were placed under the control of the organized and disciplined military forces of the nation. It would not be

necessary to have a soldier ready to put out every fire and arrest every depredator. If it were once understood that the national forests were under the immediate charge of the army, and that persons who harmed them would be dealt with after the rigorous and summary processes of military law, marauders and intruders of all kinds would be deterred from any attempt at the spoliation of Government property. Under the present system, or lack of system, these attacks are invited by the assurance that there is no danger of punishment, for although the laws may seem to be rigid they are practically never enforced.

If this system of entrusting public forests to the army were not avowedly temporary, it might be worth while to consider whether the officers of the army, being men to a certain extent of scientific training, would not make the best supervisors of such a system of forest-policy as would be the best for this country. It will be many years before it will pay to go into the refinements of forest-practice here, and perhaps no body of men could be found who could be so readily prepared in the rudiments of forest-management as the officers of our army. We are ultimately to have forest-schools in this country no doubt, and that time will come when there is a demand for skilled foresters; but is it altogether an impracticable idea to add to the course in West Point some instruction in the rudiments of forestry and to establish the nucleus of the first forest-school there upon the Government reservation? Here are 2,000 acres of forest-land, and why would this not be an excellent practice-ground if some system of forest-instruction were to be given to the cadets? At all events, this large tract of Government forest-land would offer an admirable chance for lessons in the rudiments of forest-management if the woodlands on the public domain are to continue for any time under the protection of the army.

However this may be, we venture to suggest that in the reservation of public forest which is likely to be set apart by the act which has already passed the House of Representatives, and is now before the Senate, a detachment of the army would be all the protection needed for several years to come. We refer to the bill making a so-called public park in Tulare County, California, of certain designated townships which contain the remarkable grove of Sequoias to which allusion has been already made in these columns. It might have been better if this territory had been designated as a forest-reservation instead of a park. The name, however, is of little consequence if it is understood that this grove is to be kept as it now is, a primeval forest. There is not so much need of "improving" the scenery which Nature has made as there is of protecting it from desecration, and it seems to us that for the present the most efficient way in which this can be kept from desolation by fire and axe and trampling and browsing herds is to place it under the guardianship of the army. In time to come the making of roads and other works will be necessary, but there is no need of haste in this matter. The great desideratum now is protection, and it would seem that this could be provided more effectively by the army of the United States than by any other agency.

The Nomenclature of Garden Plants.

THE report of the Committee of Nomenclature at the late Convention of Florists in Boston showed that the instances in which old plants have been fraudulently sent out under new names are less numerous than has been usually supposed. The truth is that when a dealer deliberately attempts to deceive buyers the case is usually brought to public attention, and so much comment is made that the evil seems to be much more prevalent than it really is. This Committee, which, in addition to other methods of obtaining information, sent out twelve hundred circulars of inquiry, found that a large percentage of the mistakes were unintentional, and arose from mixing labels or mistaking identity in some other way easily and naturally explained. When the immense number of garden

varieties of many plants is considered, the wonder is that buyers can make their orders with such assurance that almost every plant received will be correctly named.

This weeding out of synonyms from catalogues, however, is a small portion of the work which this Committee is called upon to do, and many of the suggestions made by Mr. Reynolds and Mr. Manning were well worthy of consideration. In the first place, it is pretty clear that some rules should be laid down for the direction of all persons who name new garden-plants—rules similar to those adopted by the American Pomological Society and now observed by all who name new fruits. The rules on the nomenclature of vegetables which the Association of Agricultural Colleges proposed are also worth considering, and some of them might apply as well to flowering plants as to vegetables. For example, the name should be short, and consist, if possible, of a single word. It should not be superlative or bombastic. A plant should not be called a hybrid when it is not a product of true species, and it may be added that garden varieties should never have Latin names. One good reason for this is that since descriptive Latin terms have been used in botanical nomenclature they should not be used in the case of plants which are sufficiently distinct for garden purposes, but which are botanically identical. Besides this, the addition of varieties will bring about at last a name too cumbersome for ordinary use. Good examples of these names could be taken from almost any nurseryman's catalogue, and such combinations as *Ulmus campestris aurea Wredei* are by no means uncommon. English names are certainly to be preferred for ordinary garden varieties, and these names, as has been well held, should not be descriptive. It would not be difficult to formulate a code of rules which could be applied to the great majority of florists' plants, and there is little doubt that if some authoritative organization like this Association should promulgate these rules new plants would as a rule be named in conformity with them.

As a branch of this general question an effort is being made to bring the descriptions of plants in catalogues to greater accuracy, and here we are at once confronted with the difficulty of describing colors. It would seem that the only way to convey an accurate idea of the color of a flower is to have some chart of standard colors to which reference can be made. As an illustration of the difficulties in this regard it was stated in the Convention that a single plant was described in seventeen different colors or combinations of colors, which ranged from "pink with a white centre" through "yellow orange red" up to "velvet shaded purple." Such fearful and wonderful colors as "garnet red tinted with rosy brick" and "black amaranth marmorated chestnut brown" were given as attempts to describe accurately the tints of some flower or leaf. The sample cases of spool-silk made by the Brainerd & Armstrong Co., which have been advertised in this paper, contain more than 200 shades, but very few of them, it was said, are found practically useful in describing flowers. On another page of this issue Mr. Orcutt attempts to use the "Nomenclature of Colors" adopted by Robert Ridgeway for the use of naturalists. Of course, if one has not this system to refer to, Heliotrope-purple and orange-vermilion will not convey a precise meaning, but if these terms and others become identified with a standard print they will be of great assistance to all who wish to describe the tints of flowers.

"Whatever contributes to render the scenes of nature delightful is amongst the subjects of gardening; . . . and nothing is unworthy of the attention of a gardener which can tend to improve his compositions, whether by immediate effects, or by suggesting a train of pleasing ideas. The whole range of nature is open to him, from the parterre to the forest; and whatever is agreeable to the senses or the imagination, he may appropriate to the spot he is to improve; it is a part of his business to collect into one place the delights which are generally dispersed through different species of country.—From *Whateley's "Observations on Modern Gardening,"* 1770.

The Clark Elm.

WE have already given a picture of a typical American Elm (see p. 287), and in this number (see p. 443) we give a winter view of another characteristic form of this tree as it appears in New England, where it is known as the "Willow-tree type." It is a magnificent specimen, standing in Lexington, and known to many, for its home is amid scenes which are memorable in Revolutionary annals. It is on the premises of the Clark-Hancock house, whose history is summarized in this tablet: "Built 1698; enlarged 1734. Residence of Rev. John Hancock fifty-five years, and of his successor, Rev. Jonas Clark, fifty years. Here Samuel Adams and John Hancock were sleeping when aroused by Paul Revere, April 19th, 1775." It is within earshot, too, of the spot where Major Pitcairn called upon the Lexington rebels to throw down their arms and disperse. It was but a stripling on that day, having been set out only five years before by the Rev. Jonas Clark named in the tablet. Its age, accordingly, is about 125 years.

The trunk forks at four feet ten inches from the ground. The special divisions of the two great branches spring lightly upward in noble arches, the branchlets at the extremities sweeping the ground even in winter, while in summer when the branches are weighted down by the leaves the whole tree presents the appearance of an immense leafy dome poised upon a tremulous edge of green. The circumference of the trunk at four feet above the ground is thirteen feet five inches. The circumference of one branch at the point of furcation is eight feet seven inches, and the other branch eight feet eight inches. The height of the tree is seventy feet, and its spread is eighty-four to ninety feet.

Our illustration is from a photograph by Mr. Henry Brooks, of Medford, and the tree is one of those whose portraits will appear in the "Typical Elms and other Trees of Massachusetts," now in course of preparation by that gentleman.

Color Notes on California Wild Flowers.—I.

IN describing the colors of the following wild flowers of California, I have taken pains to compare each with the colored plates given in the "Nomenclature of Colors for Naturalists," by Robert Ridgeway, of the United States National Museum. I have matched each color as closely as I was able in the field, with fresh flowers before me, usually in considerable numbers, so as to note the range of variation in each.

This character is frequently ignored by botanists, but with cultivators of flowers it should receive very careful attention. Ridgeway's "Nomenclature," above referred to, though not wholly satisfactory and far from complete, is still our only standard authority on the subject. To secure uniformity of nomenclature no other chart can be used with safety, unless compared with Ridgeway's first. The sample-case sent out by Messrs. Brainerd & Armstrong Co. I have not seen, but if it uses a different nomenclature from our standard, it will be as mischievous as useful. Ridgeway's "Nomenclature" may be had of Messrs. Little, Brown & Co., of Boston, and should be in the hands of every one desiring accuracy in his descriptions.

California is associated in the mind with gold and "golden" flowers. Frequent in literature are references to "fields of green and gold" and "seas of golden flowers;" yet it is doubtful if the color of gold can be matched in any flower that grows. The "golden" *Eschscholtzia* is of an orange hue, and any yellow tint is golden to the popular eye.

Fritillaria biflora, familiarly called by the children around San Diego by the name of the Chocolate Lily, is an elegant plant, related to the Crown Imperial. The plant grows from a few inches to a foot or more in height, with broad base leaves and a strong leafy stem, producing from one to five large and beautiful deep claret-brown campanulate flowers, like a spray of bells. The flowers are an inch long, slightly mottled with green. It is one of the finest species in a large genus of stately and handsome flowers.

Allium fimbriatum is a pretty plant, abundant in the mountains of Southern and Lower California, bordering the Colorado Desert. It sends up a stout scape a few inches high, bearing

twenty-five or thirty showy flowers of a very dark rose-purple color—sometimes lighter. Its Mexican name is *Lavina*.

Lathyrus venustus is the very pretty wild Pea so abundant through Southern and Lower California, in the cañons and valleys near the coast. The clusters of flowers are of a bright magenta. It is frequently taken for our more magnificent *Lathyrus splendens*, which has much larger flowers of a brilliant rose-red to crimson.

Frasera Parryi is a tall, stately biennial, growing in the mountains of San Diego County, usually from two to four feet in height. The first year the plant forms a cluster of broad radical leaves, which makes a mat on the ground, and, as the leaves are usually bordered with white, the plant is quite pretty at that stage. The second season it sends up its tall panicle of curious blossoms, with a deeply four-parted, rotate corolla, each division with a glandular and fringed pit on the upper side. The flower is scarcely an inch across, white (sometimes of a slightly greenish cast), with an apple-green spot on both sides of the hairy glands; while the midveins from the glands to the apex of the divisions are Heliotrope-purple. The corolla is thickly dotted with fine spots of Heliotrope-purple. It is a curious and striking plant, well worthy of cultivation, like nearly all herewith mentioned—many of which, indeed, are in cultivation in Europe, if not in America.

The Mohave Desert, in San Bernardino County, yields a multitude of beautiful flowers, none of which probably exceed in brilliancy of coloring the orange Mariposa Tulip (*Calochortus Kennedyi*). I have only been able to compare dried specimens of this lovely flower with Ridgeway's nomenclature, by which I would describe its color as between a Chinese orange and an orange-vermilion. If I may trust my memory through the eight years since I collected this plant I should say that its color when fresh is the same as when dry. The plant seldom exceeds four to six inches in height, and produces several of its showy flowers, which are about two inches across.

A large plant of *Cereus Schottii*, from San Quintin, Lower California, is just blooming in the garden (July 7th, 1890). This gray-headed "Old Man" Cactus, known by the Mexicans as the *Carambaya*, called by some of them the *hombre viejo* or *cabeza vieja*, according to Brandegee, and in Sonora known as the *Zina*, *Sina* or *Sinita* (Schott), is a tall, stately plant ten to fifteen feet or more in height. The flower is of a delicate shade between rose-pink and flesh color, an inch long and less than an inch across, quite pretty, but very insignificant beside the huge plant that produces it.

Opuntia prolifera, the common Chollas Cactus so abundant in the vicinity of San Diego, has flowers of a wine or pomegranate purple, which are very pretty, but are so well guarded by a multitude of formidable spines as to almost repel admiration. The fruit is proliferous, the seeds almost invariably abortive. The plant forms impenetrable thickets, covering quite extensive tracts along dry water-courses, on hill-side and mesa, attaining a height of four or five feet or more, and is one of the most characteristic features in the vegetation of Southern California near the coast.

Orcutt, California.

C. R. Orcutt.

Diseases of Chrysanthemums Caused by Insects.

THE cultivation of Chrysanthemums has come to occupy such a large place in floriculture that any disease which affects their growth and beauty naturally causes annoyance if not pecuniary loss to the growers of these popular flowers. They have not been subject to many injuries in the past, the best known being caused by Aphides commonly called green or black "flies," and by a fungus or "mildew" which attacks the leaves and affects their appearance and vitality. Gardeners have learned how to avoid or combat these pests, but there is another trouble which they have suffered from for years for which no definite cause has been given.

In describing this disease of the Chrysanthemums many gardeners use the terms "blinding" or "disbudding," meaning that the ends of the branches look as if stunted, the leaves are crowded together and the internodes much shortened; and worst of all, the flower buds become abortive and the expected blossoms are not produced. It was thought that these effects might be due to minute fungi, but expert fungologists were unable to detect any fungus growth in badly affected specimens submitted to them.

It is generally the practice of gardeners to start the Chrysanthemum cuttings in frames or under glass in spring, and after danger of frost is over to transplant them to the open ground. Aphides soon become abundant on the tender terminal shoots, and these are followed by other insects of the bug family, whose relation to the Chrysanthemum is little known. Few

caterpillars or insects of other orders attack the plants. With the object of discovering if possible the cause of this blight of the flower buds, a careful examination of the Chrysanthemums in different localities about Boston was made last year and have been continued the present season. The results although incomplete show conclusively that the distortions are due to the work of bugs of one or more species, which, with their slender beaks, pierce and suck the sap of the leaves and tender stems, causing the arrest of growth and giving them the familiar tufted appearance.

Probably the worst insect—one which is more abundant on the plants than all the other species together—is a leaf-hopper (*Cicadula quadrilineata*) which was first described in 1884 by Professor S. A. Forbes in his Fourteenth Report as State Entomologist of Illinois, and which is stated to have been abundant in wheat fields and injurious to Indian corn in some parts of that state. When at rest the general color of this little insect is an iridescent light yellowish green. The head is pale yellow with black eyes, and several distinguishing but variable and small black spots in front of the head between the eyes. It is very active, and on account of its color as well as diminutive size is not easily seen either on the plants or when flying, unless close and careful attention is given.

One or two larger species of leaf-hoppers are occasionally found about the plants, but they are usually rare and very probably their presence is accidental.

The common Tarnished Plant-bug (*Lygus lineolaris*) is always present in considerable numbers and doubtless is very mischievous. The Four-striped Plant-bug (*Lygus lineatus*) punctures the young leaves and causes brown spots in them, which are often so numerous as to result in the drying and withering of the foliage. This bug is bright yellow, about three-tenths of an inch long, and has a broad and a narrow black stripe down each wing cover. Both this and the Tarnished Plant-bug feed upon a great variety of vegetation.

The Insidious Flower-bug or False Chinch-bug (*Triphleps insidiosus*) is one of the smallest bugs found on Chrysanthemums. The general color is black, but there is a broad yellowish white or light reddish band across the front half of the wing covers, while the ends appear colorless.

This little bug has a favorable record as preying upon other injurious insects, and whether it is injurious or beneficial to the Chrysanthemum has not been clearly ascertained. It is usually present in considerable numbers, and may be found, in various stages of growth, hidden in the crevices about the buds and young leaf-stalks.

Plagiognathus obscurus is common about the plants, but whether it injures them or attacks other insects is not known, as little seems to have been recorded of its habits. That it may be a serious enemy of the plants may be inferred from the fact that observation on three or four specimens of a closely allied species of bug showed that they were capable of keeping the young fronds of a Fern (*Aspidium*) in check and causing them to become stunted and brown colored. Besides these bugs several other species are occasionally found; and there are also many small flies noticeable about the plants. The flies are often of bright or metallic colors and are harmless, probably being attracted to the plants by the sweet "honey dew" from the Aphides.

Gardeners usually care more for a means of destruction than a description of an insect, so that only the names or most obvious characters of the injurious bugs are given here. The detailed and often lengthy descriptions may be found in various writings on insects.*

All of the insects named are true bugs, having no jaws, but obtaining their food by sucking the juices of plants (or, as in the case of *T. insidiosus*, the juices of other soft insects) by means of their slender beaks, which they insert within the tissue. They thus avoid taking any poison which may be applied on the leaves and which would be effectual in destroying foliage-devouring larvæ. Consequently, recourse must be had to substances which compass their destruction by suffocation. Fresh Buhach, or Pyrethrum Powder, is one of the most effective remedies against many insects of this kind, and it has the advantage of not being injurious to the plants. By the use of a hand-bellows it may be dusted on dry; or, it may be applied in a liquid form at the rate of a tablespoonful to a gallon of water. It should be dusted or sprayed forcibly, so as to come in contact with all the insects. This remedy is

* *Lygus* (= *Phytocoris*) *lineolaris*, Harris' Insects Injurious to Vegetation, pp. 203-202.

Triphleps (= *Reduvius* or *Anthocoris*) *insidiosus*, in Description of the Insects of North America, by Thomas Say, edited by J. L. Leconte, vol. i., p. 357.

Plagiognathus obscurus, P. R. Uhler, in Hayden's Fifth Annual Report of the United States Geological Survey (1872), p. 418.

considered too expensive by many people, and for such there is a cheaper and possibly more effective alternative in Kerosene Emulsion. But some care is required in the application of this, because, if too strong, it is liable to injure the foliage. The kerosene must be first mixed with milk or soap,—that it may readily become incorporated with water when diluted—soap being generally considered the better for this purpose.

In two gallons of boiling water dissolve a pound of common hard soap; after the soap is dissolved, and while still boiling, but moved from fire, add half a gallon of kerosene oil. This must be stirred briskly or churned until the oil will not rise to the top when the mixture is allowed to stand and cool. When used, this emulsion should be diluted with five or six gallons of water. It should be strongly sprayed upon and about the plants by means of a force-pump or powerful syringe. The finer and stronger the spray the better the results are likely to be, because the Cicadulas take to flight upon slight alarm, and the spray should be far-reaching enough to overtake and thoroughly wet them. Particular care should also be given to spraying the under sides of the leaves and the close tufts of foliage, because it is in such situations that a great many of the insects are concealed and carry on their worst work. If it is found by experiment that the plants will bear a stronger emulsion less water should be added, but the condition of the plants and the state of the weather are factors which have to be considered in determining this question.

The dusting or spraying should be often repeated, because, as already stated, all these insects are known to feed on other kinds of plants, and they may easily migrate from them to the Chrysanthemums. The insecticide will kill the useful aphid-eating larvæ of the "lady-bird" beetles, but this cannot be avoided. The plants would be safe if covered with fine netting or gauze stretched over light frames.

Figure *f* in the drawing represents the fly and larva of an insect which, under various names, has long been known as being very injurious to the foliage of the "Marguerite" or "Paris Daisy" (*Chrysanthemum frutescens*) and some allied species, and also to Cinerarias, Eupatoriums, etc. Last season a few were found mining in the leaves of some choice Japanese Chrysanthemums, and as it may become troublesome it is noticed here that gardeners may be on their guard against it. The larvæ or little maggots live within the tissue of the leaves, and make long, irregular burrows or mines, which are easily traced by the lighter color of the surface. These mines are often so abundant that the leaves are completely destroyed, and even where they are but few they cause serious disfigurement. To pick off and destroy the infested leaves as soon as noticed is the only remedy known. If not destroyed the little maggots change to pupæ within their mines, and soon afterward small ashy gray flies come forth, and proceed in the work of perpetuating the species and accomplishing further destruction.

These flies have been most commonly referred to as *Phytomyza nigricornis* and *P. affinis*. But Mr. F. Kowarz, of Austria, a specialist on this group of flies, after examining a number of specimens collected in the vicinity of Boston, has decided that they are a distinct species, and has proposed the name of *Phytomyza Chrysanthemi* for them. His careful and detailed description has not yet been published in this country. It is most probable that the species came with plants from Europe.

Eristalis tenax, Fig. 55 (*e*), is a fly about which there has recently been some discussion, in an entomological journal,* regarding its probable pollenization of the Chrysanthemums. On the approach of cold weather in the autumn it is often found in considerable numbers in greenhouses, where it passes the remaining days of its life in resting upon the flowers or darting about with a loud buzzing noise. In the journal referred to, Mr. John Thorpe, the well known florist, is quoted as stating that he had never seen the insects outside of his greenhouses, and never before the first week in October. They are certainly most noticeable at that time, but are to be found about a great variety of flowers in our gardens from May or June throughout the rest of the season. Among great numbers of other insects these are usually overlooked or mistaken for honey bees, to which they bear some superficial resemblance. But *E. tenax* has only one pair of wings, and is perfectly harmless, inasmuch as it can neither sting nor bite.

It is often found in our dwellings in the autumn. Around Boston, gardeners complain of injury to white Chrysanthemum blossoms by a dark fluid excrement which these flies eject on the petals, and for this reason they are usually destroyed.

They are found over a large portion of the northern hemisphere, but were first noticed in America at Cambridge, Mas-

sachusetts, in 1875. The larvæ, known as "rat-tailed maggots," live in offensive pools of mud and water. Pools around manure piles are favorite haunts; and, no doubt, the barrels and tubs of manure and water often kept in and about greenhouses for fertilizing purposes facilitate the multiplication of the insects. In the open air the flies cannot avoid distributing pollen of some kinds of flowers, although it is done in a haphazard way. Whether they are useful in pollenizing or cross fertilizing the Chrysanthemums could be determined by a few simple experiments.

The illustration is made from drawings by Mr. W. H. Denton.
Arnold Arboretum. J. G. Jack.

Plant Notes.

Pyrus nigra, Sargent.

PROFESSOR SARGENT'S notes upon *Pyrus arbutifolia* (page 416) are interesting and valuable, and I am confident that he is right in making two species out of the plants which we have thrown loosely into one. His characters of separation are well drawn and important. I have noticed the distinctions he records, and but a few moments before reading his article I had been studying my specimens, and had come to the conviction that we have two species.

His note recalls a most interesting case of synonymy. In my garden I have two plants, top-worked on *Pyrus Aucuparia*, which I bought of a leading nursery as *Amelanchier ovalis* and *A. alpina*, both of which are the *Pyrus nigra*, as I shall hereafter call our black Chokeberry. I suspect that these have been introduced from Europe under this name. The one called *Amelanchier alpina* is a slower grower than the other, with leaves somewhat narrower and less glossy above, but the differences are such as could be easily produced by cultivation. Of the same nursery I ordered a tree of the Medlar, and procured this same *Pyrus nigra*!

It may not be generally known that the Chokeberry can be used as a stock for dwarfing Apples. I have fruited the Crab Montreal Beauty on it, and have worked other Apples on it successfully. My plants were unfortunately destroyed, so that I have no knowledge of how long such plants would persist. A brief record was made of these trials in the *Country Gentleman*, 1886, page 676, and Bulletin 31, Michigan Experiment Station, page 93.

Foreign Correspondence.

London Letter.

MUTISIA DECURRENS continues to be a success against the sunny wall of one of the museums at Kew. All the Mutisias, and this one in particular, which is the best in a garden sense, prove awkward customers under cultivation, at least in the majority of English gardens. Even at Kew, where it is now in splendid health, this is the first decided success against many equally decided failures. This week I counted on the plant fifty-three fully expanded flowers, every one at least four inches across, as elegant as the most perfect of daisy-shaped flowers, and the color a brilliant flume-like orange-yellow. If one could be certain that the plant would behave like this whenever placed against a sunny wall, he need not hesitate to plant it largely and recommend it to every one who wanted a magnificent perpetual summer-flowering wall plant. The border in which this Kew specimen has done so well is an ordinary one, and the stems are tied loosely to a wire trellis. To keep the slugs from eating off the young shoots, of which they are very fond, a mulching of small pieces of coke is placed over the ground where the shoots push up, and this acts perfectly as a protection. The climate here is not too cold for this plant, but it is possible that a hot, dry summer would be too much for it. This year has been considerably below the average in regard to sun-heat and light, and above, in regard to moisture; a bad summer for gardening generally, but good for some things, and apparently the Mutisia amongst them. I have heard of good examples of this plant having been grown in a bed along with Rhododendrons, upon which the stems were allowed to climb.

GENTIANA ASCLEPIADEA.—A mass of this plant, fully two yards in diameter and nearly a yard high, with its scores

**Entomologica Americana* (Brooklyn, New York), May, 1890; also additional notes in July number.

of stems heavily laden with rich blue flowers, is now the most attractive herbaceous plant in the rock-garden at Kew. It is planted in a moist, partially shaded position in rich loamy soil, where it has grown into its present dimensions from a small plant in about five years. Every year hundreds of seedlings spring up about it, proving that the plant is as happy and as much at home as if it were on the Swiss mountains. Indeed, it is even happier, according to Mr. Dewar, who has just re-

the plants and the size and rich colors of the flowers. They were obtained from Messrs. Hallock & Sons, of Queens, New York, who profess to have obtained them by crossing *G. Saundersii* with some of the finest popular kinds. These at Kew are not named, but they deserve to be, and the raisers may be congratulated on the excellence of their seedlings. Some of the spikes are fully six feet high, and they are well furnished with flowers, all of them larger than any *Gladiolus* we have

Fig. 55.—Insects Affecting Chrysanthemums.—See page 439.

- (a) *Cicadula quadrilineata*. (b) *Lygus lineolaris*. (c) *Triphleps insidiosus*. (d) *Plagiognathus obscurus*. (e) *Eristalis tenax*.
(f f) *Phytomyza Chrysanthemi* fly and larva, with *Chrysanthemum* leaf (g) showing mines of larva. All enlarged except the leaf.

turned from Switzerland, and declares that nowhere did he see this species so fine as it is under cultivation here, and he saw acres of it. In the gardens at Belvoir Castle it is equally vigorous. It ought to become a favorite for borders, or even as a specimen on lawns. There is a white-flowered variety of it.
NEW GLADIOLI.—A bed of seedling Gladioli, comprising some half a dozen kinds, now flowering finely at Kew, is attracting much attention because of the extraordinary size of

seen, whilst the colors are brilliant as well as variable. In another part of the garden there is a fine bed of the best of the hybrids raised by Monsieur Lemoine, of Nancy, from *G. purpureo-auratus* crossed with some of the *G. Gandavensis* kinds. These beautiful plants have already won a first-class reputation, their colors being exceptionally rich, the flowers large, and the plants as easy to manage as the ordinary varieties. Monsieur Lemoine also raised some hybrids from *G. Saundersii*

and *G. Gandavensis*, which are apparently very similar to those raised by Messrs. Hallock. The latter are, however, superior so far as regards the size of the flowers and the robustness of the plants, a difference which, however, may be due to the unusual size and health of the bulbs as grown in America by Messrs. Hallock. There can be no question of the beauty and decorative value of these Saundersii hybrids.

G. DECORATUS.—This is a new plant, and is one of the most beautiful of the species of *Gladiolus* known in gardens. It is now in flower for the first time at Kew, whither it was sent by a missionary in 1887 from the Usagara Mountains on the east side of Africa, near Zanzibar. Although but recently brought into cultivation, the species has been known since 1858, when Dr., now Sir John, Kirk found it while in company with Dr. Livingstone. The plant has bulbs scarcely an inch in diameter, narrow, sword-shaped leaves two feet long, and a flower spike three feet high, bearing ten flowers. These are three inches long, two inches across the mouth, the lobes recurved at the apex and the color a bright scarlet with an oblong conspicuous blotch of bright yellow on each of the three lower segments. These blotches are very ornamental. The plant appears to be quite happy under ordinary cultivation and it promises to seed freely. As a garden plant it should become a favorite on account of the distinctness and beauty of its flowers. It may also prove valuable in the hands of the hybridizer.

G. PRIMULINUS.—This was obtained from the same source as *G. decoratus* and flowered at Kew lately. It belongs to the broad-leaved, robust growing section represented by *G. draccephalus*. The flowers are as large and similar in form, but they are of a uniform pale Primrose-yellow. The plant was lately shown at a meeting of the Royal Horticultural Society. It is ornamental and should become a favorite with bulb fanciers. It may be well to mention here that to prevent possible misunderstanding, the plants sent from Kew to meetings of the Horticultural Society are not submitted to the Committee of Awards; consequently no plant from Kew ever obtains a certificate.

TRITONIAS.—These and the *Montbretias* are first-rate summer bedding plants. At Kew they are massed in circular beds eight feet across, and they make a great blaze of color from the middle of August till the end of the summer. In open places on the lawns, where they may be seen a long way off, they are very effective. They are quite hardy, and they increase so rapidly that a small clump, if well planted and let alone, will in a year or so grow into a great mass. Or, they may be lifted after flowering and dried in the same way as *Gladioli*. *T. aurea* is a well known summer flowering bulb, but the two varieties of it called *Maculata* and *Imperialis* are great improvements on the type.

MONTBRETIA POTTSII is almost as good as the *Tritonia*, but better than either is the hybrid raised from them by Monsieur Lemoine and named *T. crocosmiaeflora*. In rich soil this is almost a yard high, and the branched spikes are crowded with large orange and bronzy crimson flowers. The size of the flowers varies with the quality of the soil, but even in poor soil the plant is a success. Then there are about a dozen other named kinds from the same parents as *T. crocosmiaeflora*, but except in one or two there is not much difference between them. *Gerbe d'or* is, however, a beautiful plant, quite as tall and free-flowering as the best, the flowers being large and bright yellow. I have seen *M. Pottsii* at the foot of an old wall facing south, where it had become established, and formed a broad fringe of bright green leaves, changing in autumn to a cloud of orange-red flowers. Those here named would be equally effective in similar positions. Certainly these plants do not fill as large a place in gardens as they well might.

Cultural Department.

The Propagation of Hardy Herbaceous Plants.

THE time is now at hand when these plants may be propagated from cuttings and seed with the best results. It is far better to take cuttings before they have been subjected to frost and their growth checked thereby—that is, if the convenience of a greenhouse is at disposal where a temperature of fifty degrees can be maintained at night. Another advantage is, that cuttings taken now, rooted and potted, may be hardened off in a cold frame and safely wintered there with very little trouble or expense. Such plants as *Veronica sub-sessilis*, *V. amethystina*, *Anthemis tinctoria*, choice double Hollyhocks, *Heuchera sanguinea*, all the perennial Candytufts, *Amerias*, *Arabis*, *Alyssum saxatile*, *Genista tinctoria* and *G. sagittalis*, Pentstemons, *Salvias*, *Sedums*, *Desmodium pendu-*

liflorum, the perennial Peas, such as *Lathyrus latifolius* and the beautiful white variety, may be easily rooted now; the long shoots may be cut up in short pieces and they root speedily. The tufted *Phloxes* may all be rooted now and will make nice flowering plants next spring, as, indeed, will all of the above.

There is but one way to propagate the double *Lychnis Chalcidonica*, as it does not seed. We cut off the flowering stems as soon as they are past, when nice young shoots start from the base at once, and these make excellent cuttings and root readily. Of *L. viscaria*, *L. vespertina* and *L. diurna*, the double varieties all root readily. We have never found fall propagation of the tall-growing garden *Phlox* a success; they root fairly well, but winter badly, and any such plants should be lifted in fall and the young growths taken off in spring, when all will root and make strong flowering plants, and the old plants, after furnishing the cuttings, may be transferred to the border and will flower well also. The various *Dianthus*es, such as *D. plumarius*, may be carefully divided and those portions without roots used as cuttings. The choicer sorts of Clove Pinks and Scotch Pinks are best layered now and potted up later on, to be placed in the cold frame. This is necessary even though it is not desired to increase the stock, for these choice Pinks are apt to winter badly sometimes, and, moreover, one cannot well have too many or be without them altogether. With the double *Pyrethrums* our best success has always been obtained by lifting the clumps in March or when the young growth is just above ground and dividing them carefully, leaving two shoots to each portion. The other shoots may be taken off and placed in the cutting bench, where they root readily, while the rooted pieces may be potted and placed in a cold frame, and afterward transferred to the open ground in May, where all will flower, even the rooted cuttings. These *Pyrethrums* are now in great demand, and are annually imported by the thousand. Imported plants always start into growth on the voyage, and need very careful treatment on their arrival. We have found it best to pot them always, and place in a cool shady place for a few days and gradually harden them off to the sun and light, planting them out with the other things in May. The same remarks apply also to double *Delphiniums*, *Potentillas* and herbaceous *Phloxes*. It has been aptly remarked that, with importations of these plants, everything depends on the packing. Our own experience has always gone to prove the excellent way in which French goods are packed, and the many things there are yet for the English firms to learn in this matter. The freight charges on French goods are high, but the results obtained and the few losses much more than compensate for the same.

Many people may think that their gardens are already full and that there is no need of propagation; but how many are the ills that affect plants and how they seem to multiply when the specimen is an only one! How pleasant it is to know that in the reserve ground are others only waiting to take the places of such as are joining the majority or are in need of division which may check them considerably for a season, to say nothing of being able to gratify the longing glances of a friend who finds the tenth commandment very difficult to keep!

E. O. O.

The Wild Garden.

IT is the last of August and the wild garden is still brilliant with flowers. Several Sunflowers are in bloom. One of the prettiest comes from Texas—*Helianthus cucumerifolius*. It is an annual from two to three feet in height, very branching, and with glossy, shining foliage and long, slender, spotted stems, each terminated with a flower with a dark or nearly black disk, surrounded with broad, thick-set rays. It is charmingly graceful swaying in the breeze, and is beautiful as a cut flower. It commences to bloom about the middle of July and continues until frost.

Another very pretty one is a variety of *H. latiflorus*. This is a perennial and begins to blossom by the middle of June. It is little more than two feet in height, much branched, and with yellow florets, which, together with the numerous deep yellow rays, make it very conspicuous. At this date it is one mass of bloom.

A third species in flower has thick rigid leaves and yellow disk and broad rays nearly two inches in length. It is not so branching as either of the above, consequently not so many flowers on the plant, still it is quite showy and desirable. Were it not an annual I should call it *H. rigidus*.

H. angustifolius, our narrow-leaved New Jersey species, is just beginning to blossom. The leaves are long and grass-like,

with rough revolved edges. The plant is very branching and when in a good situation attains a height of six feet or more. The flowers have a dark disk and bright, almost orange-colored rays. It is later coming into flower than any other species in my garden.

The pretty Cone-flower (*Rudbeckia bicolor*) has been in blossom since July. This is a showy species from Texas with a dark cone-shaped disk and almost orange rays. It is not

flowers make a fine show during the last half of summer. And now several species of Golden Rod are beginning to add their graceful plumes among them. But the wild flowers at this season are not all yellow. The pretty little rare *Coreopsis rosea* is blooming among the Polygalas. This has rose colored rays and yellow disk. It commences to bloom about the 1st of August and continues in flower a long time. And some shrubs of the sweet scented *Clethra* are still in blossom.

The Clark Elm, Lexington, Massachusetts.—See page 438.

much above a foot in height, but is very branching, and the flowers remain fresh a long time, the rays finally withering without falling. It is an annual and from all appearance will remain in flower until frost.

Polygala lutea, with heads of bright orange about the size of Red Clover, has been in blossom all summer, and is still beautiful among the Ferns and other low growing plants.

The yellow-fringed Orchid (*Platanthera ciliaris*) is just passing out of flower. It has been charmingly beautiful and stately among the wild Lilies and Ferns. All these yellow

Pancratium coronarium, a member of the Amaryllis family and a native of the southern states, has proved hardy here and has just bloomed finely. As a pot plant it did not do very well, so several years ago I turned it out in the open ground to shift for itself, not knowing that it would survive our winters. For two or three years it showed only leaves during the summer, but now toward the last of August it sends up a fine flower scape surmounted with four delicate white fragrant flowers which remain perfect several days. The divisions of the perianth are long, linear and spreading, and the

crown is of delicate texture, large and somewhat funnel-shaped.

There is nothing in my garden that presents a more striking effect at this time than a clump of Sedge or Wool-grass (*Scirpus Eriophorum*). It is about five feet in height, with brownish or rust colored, soft woolly, great drooping panicles, and the long deep green foliage is also handsome, reaching up to the brown panicles. Other Sedges are also effective at this time. The Cotton-grass (*Eriophorum Virginicum*), with light rust colored, soft, cottony heads, is one of the best and as handsome as any flower. And the foliage of some of the wild plants is no less beautiful than flowers. The Sumachs and Sweet-gum and Sassafras and Swamp-Maples are already beginning to take on color as brilliant as the gayest flowers, while others, like the Alders, Birches, Bayberry and White Fringe, are still of the darkest, deepest green.

Vineland, N. J.

Mary Treat.

Some Native Ferns.

THE Hay-scented Fern (*Dicksonia pilosiuscula*) is the only representative we have of this genus in the United States. According to Lyell's "Hand-book of Ferns," there are twenty-nine known species of *Dicksonia* in the world, but these are mostly natives of tropical climates, Europe having but one, northern Asia one, and one in North America north of Mexico. Ours is a very beautiful Fern, about three feet high, with fronds about twice as long as the stalks, twice or rarely thrice divided. It is found from Canada to Alabama, but is not supposed to occur outside of eastern North America. It comes from creeping root-stalks and forms dense beds of its finely divided fronds. It is so abundant in many portions of the mountainous districts of New England that it is the principal pest of many mountain farms, taking almost complete possession of cleared pasture-lands which are too rough and stony for cultivation. In tillable soil it is easily kept out. Although it does well in the shade in the moist, gravelly soils of mountainous districts, it seems to prefer the sun. It is one of our most valuable Ferns for cultivation, and is more extensively grown in England, where it is highly prized, than in its native country.

Scolopendrium vulgare (Heart's-tongue) is a rare Fern in America and the only species of the genus found in the United States. There are said to be only nine distinct species in the world. This one has been found in only two or three places in North America north of Mexico. One or two of these are in New York State and one in Canada. But in Europe it is more abundant and variable. It has many forms, one English writer claiming as many as a hundred varieties. Here it is seldom over eighteen inches high by one or two inches wide; but in Europe it sometimes attains a height of nearly four feet. The single fronds are somewhat heart-shaped at the base. It is a valuable hardy Fern for cultivation, but needs to be planted in a loamy or gravelly soil in the shade. It may be transplanted in early autumn or in the spring.

Pellaea atropurpurea (Clayton's Cliff-brake) is generally considered a difficult species to grow, and all efforts to grow it with ordinary level culture seem to have failed; but if its natural locality is closely copied it is not hard to manage. It is a useful Fern for cliff-work and when once established will continue from year to year. Mr. C. G. Pringle had a plant that lived without any care for twelve years in a shaded crevice of an old wall on the north side of his house, in Charlotte, Vermont. It is an interesting and curious little evergreen, with wiry, brittle stalks from two or three inches to a foot high. It is usually found on shaded limestone cliffs in tufts of two or three stalks, to a hundred or more in large specimens. In its peculiar habitat it is found from Canada to the Rocky Mountains, and south to Alabama, Mexico and South America.

Aspidium spinulosum (Spinulose Wood Fern) is a common half evergreen species about three feet high at maturity, with oblong-lanceolate fronds about twice as long as the stalk. These are twice or three times divided, fine and pretty. There are chaffy scales the entire length of the stalk and rachis of the frond. It is found in moist, shaded woods from Newfoundland to Oregon, and south to the southern Alleghenies. There are three forms in New England, the typical species, the var. *intermedium* and var. *dilatatum*. The latter is the largest form and grows in mountainous districts. It is a good Fern for shaded slopes and is perfectly hardy. Early autumn or spring is the best time for transplanting.

The Virginia Chain Fern (*Woodwardia Virginica*) is the best bog Fern we have and will thrive in wetter locations than any other American species. It is useful for bogs, wet margins of ponds and streams, and, unlike most other Ferns, is not affected by stagnant water. In fact, it is often covered with water

in the spring or in very wet seasons, and at such times is a difficult Fern to procure from its habitat. Its height is from two to four feet, with stalks and fronds about the same length, twice divided, and from four to eight inches across at the widest part. Though not a common Fern, it is abundant enough in its peculiar localities from Canada to Florida and as far west as Arkansas. It will live in drier soil with ordinary culture, but a wet, boggy soil is its most natural home.

Southwick, Mass.

F. H. Horsford.

Notes on Shrubs.

IT has been remarked that the Japanese *Viburnum Sieboldi* did not produce much fruit in this latitude. This statement would appear to hold true only during the early years of the growth of the plant, and as it becomes older the flowers are more generally followed by fruit, as is the case with numerous other plants. *V. Sieboldi* grafted on stock of *V. dentatum*, and now over ten years old, is very freely bearing fruit in the Arboretum this season. Unlike most other species in the genus, the drupes in the compound, slightly convex cymes of this appear to ripen gradually and in slow succession, the earliest changing color and becoming soft soon after the middle of August, and the latest not showing the same evidences of maturity until the first or second week of September. The fruit is not strikingly ornamental, being light red above and greenish beneath up to the day of ripening, when it becomes black with a blue bloom and also very soft, and soon afterward it shrivels and falls off. The pulp is dark and of peculiar taste, and so intensely sweet that it is disagreeable. After handling the soft fruit, a sticky, elastic residue remains on the hands. In size and shape the drupes have some resemblance to those of the common Wayfaring-tree (*V. Lantana*), but in the latter they are usually not so regular and smooth, and the enclosed seed is much thinner and broader. This plant has been and is still sold under the name of *V. Japonicum* or *V. Japonicum latifolium*.

The rare North Carolina Huckleberry (*Vaccinium hirsutum*), of which a figure was given in the last volume of GARDEN AND FOREST (page 365), gives a promise of being valuable in cultivation here as one of the latest of its kind to ripen fruit. The little plants in the Arboretum begin to flower early in June, and the earliest berries mature in the last days of July. The best period of fruitage appears to be about the middle of August, but berries remain on the plants until early September. The hairy character of the shining black fruit would doubtless be against it for market purposes, but upon eating it the hairs are not so noticeable or objectionable as might be supposed; and in other respects the berries are very palatable, being juicy and of pleasant flavor.

Although the Cowberry (*V. Vitis-Idæa*) naturally haunts high latitudes and altitudes, being rarely found in other situations, it may be made to grow and fruit in cultivation if given a moderately moist and cool, but not too shady, place. The bright red berries begin to ripen here about the middle of August, and they have the same acid, slightly bitter and mealy quality which distinguishes them when growing wild on the White Mountains of New Hampshire. Although hardly pleasant tasted when raw, they may, with a little cooking, be made into refreshing and pleasant drinks and sauces.

When writing of *Euonymus nanus* some European writer has expressed the opinion that it probably bore little or no fruit in this country. *E. nanus*, however, fruits quite freely in the vicinity of Boston, and the seed within the pods is fully and perfectly developed. It is the earliest species of the genus to mature fruit, the pretty pink pods opening about the middle of August and disclosing the orange colored arils. The narrow, very dark evergreen foliage and the neat, compact habit of some of the best forms of this species make it a charming and attractive little shrub for using in many situations in the garden where showy blooming plants are not a desideratum.

Arnold Arboretum.

7.

Saccolabium Hendersonianum is the name of a charming little Orchid, which, unfortunately, is not seen often enough, owing chiefly to its scarcity in the market. In a few collections in England, however, it is found to grow vigorously and flower freely. From one of these collections—that of Major Mason, of Warwick—a specimen was recently sent to the meeting of the Royal Horticultural Society in London, where it was generally admired by the Orchid-loving fraternity. In habit the plant is dwarf, with distichous, strap-shaped, leathery leaves about six inches long and more or less recurved. The flowers, which are compactly arranged on a stiffish, erect raceme, and average as many as forty in number, have beautiful rosy pink

sepals and petals, the color reminding one, as Professor Reichenbach once remarked, of the flowers of a pretty West Indian Orchid—*Rodriguezia secunda*. The lip, which is in reality more in the way of a spur, is of a crystalline whiteness, occasionally tinged with pink at the tip, and is somewhat like an oblong inflated bladder between the broad lateral sepals.

There is no definite information to be found on record of the precise origin of this species, but it is generally supposed to have been first discovered by Mr. Stuart Low in Borneo as long ago as 1862. It was not, however, until about 1874 that it found its way into cultivation, and was soon after flowered for the first time in England in the nurseries of Messrs. Henderson, of St. John's Wood, a circumstance which led Reichenbach to name it in honor of that firm in due course.

Being a native of Borneo, *S. Hendersonianum* should consequently be grown in a tolerably warm and moist house. Baskets which can be suspended from the roof, so as to afford as much light as possible, are the best receptacles for the plants, with a light compost of fresh sphagnum and a little fibrous peat. Blocks or rafts may also be used, but if so, more attention to watering will be necessary. At the approach of summer, and during the entire hot season of the year, care must be taken as to shading, for many of these fleshy leaved Orchids are very susceptible to concentrated heat through glass.

Isleworth, London, W.

John Weathers.

Schubertia grandifolia.—A plant of this set in the open ground in late June is now profusely in bloom. It is a very strong grower, with semi-woody white stems. The leaves are lanceolate, some five inches long by three inches wide, and as they mature, are spotted brown. The figure by Mr. Faxon in GARDEN AND FOREST (page 369), while accurately reproducing the form of the plant, cannot, of course, give a complete expression of the beauty of the pure white flowers with the brownish calyx. The flowers are of very firm substance and of smooth surface, except just over the constricted throat, where they are furnished with numerous fine hairs one-fourth to three-eighths inches long, set horizontally. The office of these hairs would seem to be the brushing of the pollen from visiting insects. The organs of reproduction are all concealed in the swelling under the throat, and no color of anthers or stigmas relieves the white of the flower. As this plant seems to grow as well in the open air as under glass, it is likely to prove a desirable addition to open air vines (climbing by twining stems), as the appearance of foliage and flowers is pleasing. The foxy odor of the young foliage is less disagreeable in the open air than it is under glass. When the plant is in bloom the somewhat heavy, fruity odor of the flowers will perfume a large house. A well grown plant will cover a space of say three feet by twenty. It is readily propagated by cuttings or seed, from the latter of which it will come into bloom in from twelve to fifteen months.

Elizabeth, N. J.

G.

Gordonia Altamaha (pubescens).—This is one of the most beautiful of flowering trees, and just now it is in full flower here. It has been blooming for several weeks and will continue to do so until frost stops it. Philadelphia is fortunate in having a number of good specimens of this rare tree. It is to be found not only in private collections, but there are several in Fairmount Park. The original tree in Philadelphia is the one planted by Bartram himself in the historic garden in West Philadelphia which still bears his name. This tree was supposed to be dead, and in fact it did die to the ground, but on a recent visit to it I observed a sucker of several feet in length from a portion of the stump beneath the ground. It would be a most desirable thing to save this remnant of the parent tree, but as the place is now but little more than an open common, its preservation is doubtful.

In the garden of William De Hart, Woodland Avenue, Philadelphia, stands a fine example of this tree. It is, perhaps, twenty-five feet high. It is not a perfect specimen because somewhat crowded by other trees. It is, however, doubly interesting because raised by layering a branch of the original tree in Bartram's Garden. At this time of the year it often displays as many as 200 expanded flowers at once. The large, single white, Camellia-like flowers are extremely beautiful.

How far north this tree would thrive I do not know. I can say that in the hardest winters we have here it is never injured in the slightest degree, showing that it can be planted much further north than this.

The more tender species, *G. Lasianthus*, is thriving with us. Our plants have flowered profusely this year, though but two to three feet high. While very pretty, the flowers are not much more than half the size of those on *G. Altamaha*.

Germanstown, Pa.

Joseph Meehan.

The Forest.

The General Condition of the North American Forests.—I.

THE article which follows is the first part of a translation of Chapter I. of Dr. Heinrich Mayr's work, "The Forests of North America." Dr. Mayr paid two visits to this country, and his studies among our trees were made primarily for the purpose of estimating their probable economic value for introduction into German forests. It will be seen, however, that he became interested in the problems of forestry, which Americans must solve for themselves. It is well that we should know how these problems present themselves to the eye of a skilled observer from abroad, and although we may dissent from some of his conclusions and question a few of his statements, his general view of the subject in its broader lines will be accepted as correct by thoughtful readers. We hope to give the remainder of this chapter in an early number:

When the first European landed in the new hemisphere, an immeasurable area of forest lay before him: Unbroken, undisturbed, it stretched from the southernmost part of Florida to the coast of Labrador, through thirty-five degrees of latitude, and from the Atlantic coast to the borders of the prairie, fully twenty degrees of longitude. If we reckon the average length as twenty-five degrees of latitude and the average breadth as twenty degrees of longitude, we see that this primitive forest covered an area ten times as great as that of the German Empire. What exists of it to-day we can only estimate. Perhaps, however, a tenth part of the original area of primeval forest, or almost as much as the whole extent of the German Empire, still remains. In a hasty journey through this territory one receives the impression that it is almost all forest. With the exception of a few states, the forest is so conspicuous that the farms seem to occupy only a small part of the area. But a close examination of this forest reveals the fact that not more than a third part of it really deserves the name of forest; two-thirds are only scattered saplings, or a collection of isolated, gnarled, blighted trees, sometimes the last of their race.

The primeval forest grew in all soils, on the mountains as well as in the plain. No rock in the Alleghany Mountains was too steep to nourish single trees in its fissures; no soil of the plain was so poor and stony that it did not support a stately forest. Only swampy lowlands covered with water for the greater part of the year were without trees. This fact ought to be recorded for future generations; for to-day the forest in many places has been destroyed so completely that one might well doubt whether it ever existed.

Fifty years hence one who travels through the southern Pine-belt of the Gulf States will scarcely believe that the vast desert of pure snow-white sand driven hither and thither by the wind, once supported the most magnificent Pine forest in the world; no one will believe it possible that the bare, stony, steep slopes of the Alleghanies were once covered with a forest of broad leaved trees unrivaled in its variety and luxuriance. In fifty years it will seem incredible that the vast swamps of northern Wisconsin and Michigan were once covered with a thick growth of trees, and that forests of White Pine, centuries old, once swept about them.

If we turn toward the west and again in imagination pass over fifty years, we see a beneficent forest flourishing there, brought into existence by man on a plain which was once pronounced an almost useless desert. The forest was planted because the absolute necessity for it was felt. This western plantation thrives under human protection; but it is a misfortune that so many worthless kinds of wood have been planted, for the European species, from the young growth of which much was expected, are unsatisfactory as they approach maturity. It is to be regretted, too, that the production of fire-wood has been sought rather than the production of lumber by means of a more open system of planting; for, in case of necessity, timber-trees always make the best fire-wood.

Let us go still farther west. In fifty years it will be inconceivable that California, the beautiful fruit-garden of the Union, was once treeless. Amid magnificent forests of Australian Eucalyptus and Acacia the visitor will be inclined to doubt that he is really in America. The hard, sun-baked plains have been transformed into a sub-tropical garden under the influence of this delightful climate. But it has been an expensive task to dam up the turbid streams which pour down from the mountains during the rainy season,

and to divert them from the fertile plain. Much money has been sacrificed in irrigating the land, because the almost free watering of the country by means of the natural brooks from the mountains, has been made impossible by the reckless destruction of the mountain forest.

The path along which the country is advancing toward the future here depicted may now be plainly seen. In the description of the different regions, in subsequent chapters, an opportunity will present itself to prove the correctness of the gloomy, although not hopeless, forecast. Let us consider a few more facts that everywhere meet the observant traveler in America. Many treeless mountain slopes retain a little soil in the fissures of the rock-ledges with here and there sparse grass, which cattle crop from day to day. But the stumps of the trees are still there, and their roots, hanging like a spider's web over the bare rocks, show what a depth of soil, and the best of soil, has been washed away. One year has here destroyed what a hundred years cannot restore. The rain, which formerly was caught for the most part by the forests and slowly given up into the valley through the springs, flows now without hindrance into the lowlands, to devastate instead of to bring fertility. The noble mountains and valleys of the Alleghanies, of the Adirondacks and of the western mountain region are hastening with giant strides to the same fate.

Already many have raised their warning voices, but they have been regarded as dreamers; and the people have deceived themselves with the cry that the forest wealth of the country is inexhaustible. They cry the loudest who profit most by the present destructive methods, while the nation remains blind to the condition and the future of the forests. The nation is not informed about its own possessions even; much public land is officially reported as "covered with forest," from which the best timber was stolen long ago; much has been burned, and the rest is doomed to destruction in a few decades. And as if to destroy all hope for the future, fire is let loose to run through the forests every year.

The state of New York, to give an example, has, or rather claims to have, in the Adirondacks 780,000 acres of "unimproved" land, or woodland. The Commission appointed to inquire into the condition of the woods of these mountains found itself unable to settle the bounds of the public lands, because private persons claimed so much of the state woodlands as their own property. In a few districts the state has continuous woods, but commonly only in parcels less than 300 acres in extent. Nothing practically has been done by the state of New York to protect and preserve her woods. She does not even know their boundaries. Many settlers live notoriously by robbery from the state woods, and with fire and axe help the state to "improve" the woodland belonging to the people,—that is to say, to destroy the forest and the forest-soil.

Naturally it fares thus with national property under the protection of the general Government, since the nation pays no attention to the matter; indeed, the public lands are spoken of almost as if they belonged to private persons, or rather to nobody, and as if every citizen had not a legal interest in them.

As one goes westward from the metropolis in America, the perception of legal rights becomes less clear. According to the official report for the year 1883 the national Government some time ago allowed poor settlers and miners in Colorado to take wood from public land for the building of houses. The statute was liberal; the interpretation of it by the settlers was, however, still more so. Government officers who went out there after a few years, found lying in a mountain torrent half a million railway ties destined for the "domestic use" of a broad-gauge railway. Moreover, I read in the report of Mr. Fernow that the Government pays every year hundreds of thousands of dollars for the protection of the forests; but of what use is this, when the money disappears, one knows not whither, without the forest's deriving the least benefit from it?

To the honor of the present administration of the public lands, I may now add that the Government has awakened to the needs of these lands, and can boast that it has given back to the nation large quantities formerly held and used unlawfully by private persons and corporations.

In all mountain country, and poor land that has little agricultural value, on all banks of streams, as long as they are not regulated artificially, the preservation of the woods is demanded by nature for the protection of the lowlands. I am not of the opinion that it is necessary for the Government to retain land suitable for agriculture, in order to cultivate it as forest. The Government should concentrate its means and energies where its help alone can preserve a condition profitable to the people at large.

In consequence of the enormous wealth of the country and the productive power of its enterprising people, the Government has a large surplus in its treasury. I am of the opinion, which might be thought ridiculous in America, that there could be no more fitting return of part of the money to the people than to buy up the woods on the mountains and upon natural forest-land, in a word, all the forests which in the hands of individuals are doomed to destruction, and through legislation of the simplest kind, something like the system in use in India, to protect the forests against fire, to administer them through public officers, and, by means of a sufficient number of guards, to preserve them against thieves, hunters and tourists. The Government, and only the Government, can afford to make the sacrifice of present loss of interest upon the investment. In a few decades it would come back tenfold.

The consequences of the deforesting of the mountains are well known. We have the best examples of it in the Old World. Let us throw aside the delusion that all things are different in America; the laws of nature are everywhere the same. The soil may be better, the climate more favorable for tree-growing; but the disasters which have visited the Old World can only be delayed, not prevented, in the New. If the mismanagement and the burning go on in the old fashion, it needs no prophet to foretell the fate of the mountains and the land watered by their streams; America will soon have produced pictures which for grandeur of devastation cannot be surpassed by the mountains of the southern Tyrol, southern France and Spain. The Government owns numerous mountain forests, yet it strives to free itself of the burden as quickly as possible, and often at a ridiculous price. The giving away of the forests by the Government is equivalent to their ruin. It may be said that the Government even helps the destruction, although its duty is to prevent the spoliation of the land by a few at the expense of the whole people. Personal liberty and inviolability of property are fundamental ideas of the Constitution of the United States. But paying respect to the personal freedom of an unscrupulous person means trampling under foot the personal freedom of a thousand better men.

This proposition in itself justifies a demand by the nation that the mountain forests, no matter to whom they may belong, must be preserved. In order that hundreds of others may be able to have the full use of their own possessions, it is not unjust that the rights of one should be restricted. It is amusing to hear American opinions about the despotism of European governments which restrict private citizens in their right to property. The law for the protection of the mountain forests and land useless for agriculture, as well as lands upon water-courses, is made only to restrain the ignorant or unprincipled; the great majority of owners of mountain forests do not need the law at all, since they themselves are wise enough to know that in preserving the forests they are maintaining the value of their own property. If under the Constitution it is impossible to compel the individual to preserve his forest, the Government should have the right, for the good of all, to take possession of the property of a refractory citizen for a reasonable compensation, and manage it. The forests in the mountains or on the poor sandy plain which are now given away or sold, the Government in the next century will be obliged to buy back at great outlay, because the individual, unlike the Government, does not give anything away. The amount which the French Government has expended for reforesting denuded mountain slopes affords an instance of the costly character of such work. Let us hope that in the meantime all productive soil will not be washed away.

As before said, the forest must be preserved upon all kinds of land which admit only of tree-culture, especially upon dry, sandy soil and land of a swampy character. Such lands are common in America, particularly in the south, where they embrace thousands of square miles along the coast of the Gulf of Mexico and of the Atlantic Ocean. The noble forests of the finest Pines in the world have there been swept away, and the young growth destroyed by fire. The white sand already shines in its nakedness through the thin grass, the very picture of the future that I have described. With the last tree and its shade, the grass also will die. The great quantity of fructifying rain which this region receives cannot prevent the disappearance of all vegetation under this management; and only the sand will remain. Nothing is done here to check the evil and to save the land. Perhaps laws now exist for guarding the mountain forests; but laws that no one fears to set aside lightly, are worse than none. Wisconsin, Michigan and Minnesota contain extensive broad-leaved and coniferous

forests on level or gently rolling ground. Many hundred square miles of so-called swamps are covered with Larch, White Cedar (*Thuja occidentalis*), or Spruce and Balsam. Beneath low trees lie thick, damp cushions of moss, in which *Vaccinium macrocarpum*, Andromeda and other shrubs find a home. These kinds of growth owe their existence to the presence of this moss in the swampy places, because they can strike their roots in the decaying cushions above the surface of the stagnant water. If such swamps should be stripped of their trees, the cushion of moss would disappear under the influence of light, increased warmth, and the drier air; the light-loving swamp plants, Arundo, Typha and Carex, and nut-bearing shrubs, would then step into their place. Finally the soil would become sour, and be rendered unfit for use. Already many a resident in these new states can recall that this or that flag-swamp or grass-swamp, now impassable, was once covered with a forest, even if of little value. Such facts suggest to me the dark picture of the future of these rapidly developing states.

Correspondence.

To the Editor of GARDEN AND FOREST :

Sir.—Will you tell me what to plant in a dry, gravelly spot on the south side of a close fence as a screen? *Hydrangea paniculata* has flourished there during the two wet seasons just past. This year the shrubs are completely burned up and must come out.

Providence, R. I.

B.

[Privet is one of the shrubs which will grow in a very hungry soil, although it will grow much better in a deep rich one. Some species of *Elæagnus*, preferably *E. hortensis*, will grow on open gravelly banks, and so will the common Barberry if it is encouraged to start by placing some good soil about its roots. The American Beech will grow in poor, dry soil and will endure cutting well, and if held down to shrub size by the knife a Beech screen would have considerable beauty. But if the space is not very large, why not fill it in to the depth of a foot or two with good loam? Any one of a hundred shrubs could then be safely chosen.—Ed.]

Recent Publications.

Dreamthorp. A book of essays written in the country. By Alexander Smith. Rochester: George P. Humphrey.

The publisher of this dainty little volume has done a genuine service to a generation which rarely makes mention of the name of Alexander Smith. A few nervous lines from his earlier poems still linger in the memory of persons now past middle age, but even they have forgotten that after the chilling reception of "Edwin of Deira" Mr. Smith left off making verses and began to write essays. The series now published here was written from a sleepy, moss-grown town, where time ought to have been measured, as the author well says, by the silent dial rather than the ticking of a clock. Very pleasant bits of criticism of men of letters such as Montaigne and Lamb and Chaucer can be found in these pages, and much sound philosophy very pleasantly disguised in the form of light and confidential talk. But the book is noticed here chiefly on account of the fresh and delicate touches with which the scenery of this slumberous region is presented to the reader.

We do not know whether Dreamthorp was a real village or whether the garden from which and about which our author discourses had any existence outside of his imagination; but it would be hard to find a more pleasant description of a quiet inland country or of the thoughts which such scenery brings to the mind of a man of leisure in a contemplative mood.

Periodical Literature.

A Bulletin just issued by the Agricultural Experiment Station of Cornell University attempts to give some reasons for the almost total failure of the fruit crop in western New York the present year. All fruit-trees gave a wonderful profusion of bloom, and since the apple crop had been light last season a great harvest was expected this year. Heavy rains fell while the orchards were in bloom, and soon after the blossoms withered and the leaves of Apples, Pears and Quinces began to blight. The rains were succeeded by a severe drought, so that Apple orchards over thousands of acres seemed to be dying, while Quince orchards appeared to be scorched. It has been supposed that a cold rain in blooming-time will prevent fertilization of the flowers, but there is no

reason, it is said, for accepting this as generally true. As an evidence to the contrary it is stated that two Seckel Pear-trees of the same age and equally exposed, standing but a rod apart, were in bloom at the same time; one of these has no fruit now, while the other is loaded. In most cases this year the apples had set, and were as large as small peas when they withered and fell. At the same time the young leaves began to blight, and many other facts show that there was some intimate connection between the death of the flowers or young fruit and the blighting of the foliage. This blight is caused by the Apple Scab Fungus, which may have attacked the young fruits, or it may have impaired the vitality of the trees so far as to cause the fruit to fall. Some mycologists believe that this infection of the fruit takes place very early, but the blight of the leaf in many cases seems sufficient reason for the failure of the fruit. This Fungus, *Fusicladium dendriticum*, which destroys the foliage, is the same which causes the scab on the fruit. It has always been to some extent prevalent in New York, although of late years it has increased rapidly. The wet spring afforded a good condition for rapid growth. A closely related species (*Fusicladium pyrinum*), and by some regarded as identical with the other, attacks the Pear, and has no doubt caused much of the failure in the crop this year.

Upon the Quince a specific leaf blight (*Entomosporium maculatum*) has been very serious this year. It also attacks the fruit of Quince and Pear, causing them to crack. It is the same Fungus which preys upon the stocks of Pear and Quince in the nursery and renders their cultivation precarious. The trouble has become so serious in some places that Quince-growers are preparing to cut down their orchards. This leaf blight is not to be confounded with the well known and deadly Pear blight which sometimes attacks the Quince, but which is less prevalent this year than usual.

The injury to Apples, Pears and Quinces by the Scab Fungus is not vital, although it checks the growth of trees. As a rule the effect of leaf blight in western New York will probably be to develop a large crop of fruit-buds. Heavy crops have followed the failure from blight in former years, but if next spring should be wet and cool the Fungus may probably spread again as it has this year. Carbonate of copper is a sure remedy for this Fungus, and it is probably best to begin with it before the flowers open and to make from four to six applications before the 1st of August. Three should be made at any rate, one before the blossoms open and just after they fall and another three or four weeks later. Some of the Fungus can probably be destroyed by spraying even in August, but it is doubtful whether such application would pay. The Bordeaux mixture, the formula for which has often been given in these columns, is the best application for the Quince leaf blight.

The principal cause of the loss of the Peach crop this year is the curl-leaf, a Fungus disease. Nearly all the leaves crumpled and fell from Peach-trees last spring over a large extent of country, and the loss of foliage caused the death of the young fruit. New leaves soon appear and in strong trees little injury follows. No remedy is known for this affection, and it would be difficult to apply one, as the disease is so uncertain in its attacks. Whatever fruits escaped from the curl-leaf were attacked by the curculio, which is becoming very abundant, and which must be persistently fought if Peaches are to be grown in western New York. The old remedy of jarring the trees holds it in check, and Paris Green, at the rate of one pound to 350 gallons of water, applied early and often will be found useful. The worst enemy to Peach-growing in New York generally is the Yellows, a mysterious disease which can only be held in check by cutting out every affected tree. There is a law which compels Peach-growers to destroy trees affected with this disease, but it is not enforced vigorously. It is a constitutional disease, progresses slowly and is distinguished by premature fruits which bear well defined reddish spots which extend in the flesh. When the tree is not bearing, the first symptom is the appearance of yellowish, small-leaved, short shoots on the body and larger branches; afterward they appear in bunches. The tree soon becomes weak and yellowish throughout, the leaves are small and it dies in about three years. Yellows must not be confounded with yellowness. The first is a specific disease, the latter may be caused by anything which lowers the tree's vitality.

The most serious trouble with small fruits this year was the anthracnose or cane-rust of Raspberries and Blackberries. The growing canes became pitted with brownish black blotches, and on the weakened canes the berries dry up as if from drought. On the Station plantations the Shaffer plants especially were badly diseased. It is important in the treatment of this disease to keep the plants strong and healthy. They should be cultivated lightly once or twice a week until the berries begin to

ripen and after the berries are off, until well into August. There is reason to believe that this disease can be held in check by timely spraying with the Bordeaux mixture, and any treatment will be more beneficial if the diseased canes are cut and burned immediately after fruiting.

The Strawberry blight has been serious on some varieties and in some parts of the state. The most approved remedy is potassium sulphide (liver of sulphur) sprayed on the vines once in a week or ten days from the beginning of the growing season until the fruit begins to ripen. One ounce of the sulphide to eight gallons of water is the proper strength for the mixture. After the crop is gathered the plants may be mowed and burned over, or destroyed by spraying with sulphuric acid at the strength of one pint to six gallons of water. New leaves start soon and the plants are not injured.

The advent of rots and mildews in the New York vineyards is also chronicled, but it was to be expected, and no doubt these diseases will spread. The means are at hand, however, to keep these diseases easily and economically in check, and we have often given them. Professor Bailey concludes by urging upon fruit-growers the importance of a state law which looks toward the control of contagious plant diseases. New Jersey has recently passed such an act, and if some officer is empowered to look after the fruit interests under the law, an improvement in the health of orchards and vineyards may be expected.

Notes.

We received last week several clusters of the Green Mountain Grape from the Messrs. Hoyt, of New Canaan, Connecticut. The grapes were in fair-sized clusters, fully ripe, and in flavor and aroma were superior to any of the old varieties which ripen so early in the season.

Osbeck's Sumach (*Rhus semialata*, var. *Osbecki*) has been exceptionally full of flowers this year and they have but just fallen. Large greenish white panicles at the extremities of the limbs, and held well out above the clean foliage, make the tree particularly conspicuous at a season when there are few others in blossom. It is noteworthy that the bees seem to be especially attracted by the flowers.

Referring to the fact that Mr. Gilchrist named in his list of twenty native plants for florists' use (see page 423) Swamp Milkweed (*Asclepias incarnata*), a correspondent calls attention to a pure white form of the recognized var. *pulchra* of this species. This plant grows in great abundance, it is said, in Wayland, Massachusetts, along the road-side on the way to Saxonville, and is pronounced one of the best of decorative plants at this season.

Nearly fifty years ago the *Revue Horticole* thus described a gigantic Cactus—*Cereus speciosissimus*—then growing at Andilly, in the Valley of Montmorency: "It is an old plant and has been growing in the ground in a greenhouse for seven years past. It covers the whole surface of the wall, which is fifteen feet high and forty feet long. It produces every year from 1,500 to 2,000 flowers. From 400 to 800 are often seen expanded at the same time, when the effect of the rich colors is that of a glowing and superb tapestry."

A correspondent of the London *Garden* says that the trees in the gardens and squares of Edinburgh are as dingy as can be seen in any town, with the single exception of the Oriental Plane, which in the latter part of August was still conspicuous with its glossy green leaves; and it looked especially healthy among the fading Elms, Thorns, Sycamore Maples and Limes. The Elm seemed to the writer to suffer worst of all, because its rough leaf has an exceptional capacity for holding smut and dust, so that the middle-aged Elms in some of the streets were almost as black as the railings under them.

Colonel Pearson writes from Vineland that success in treating Grapes with copper sulphate for black rot and mildew has been as complete this year in that region as could be hoped. All those who have sprayed their vines with the Bordeaux mixture early and often have almost perfect crops of Concord Grapes. Most of the vineyards there, however, were stripped of their blossoms by the Rose bug, and only a few vine-growers have had the energy to spray their vineyards. Unless these precautionary measures are taken it would seem that for the present Grape-growing is impossible in infected regions.

The *United States Miller*, in describing an enormous flume recently built to bring water into the city of San Diego, California, states that its whole length is lined with redwood. As this length amounts to forty-five miles, it is difficult to compute the quantity of fine trees which must have been utilized in this

single enterprise. We may hope that less interesting species were used to build the trestle-work which bridges the valleys and ravines over which the flume passes, for the number of these is great, and no filling-in was allowed owing to the danger of landslips when this expedient is adopted instead of trestles.

The late Henry Winthrop Sargent was so famous in his day as a horticulturist and pomologist that it is interesting to find in *Downing's Horticulturalist* for the year 1847 an estimate of the varieties of fruits then growing in his garden at Wodeneth, near Fishkill. Apples are not included, as these he grew on another part of the estate, but, in addition to thirty-one varieties of foreign Grapes grown under glass, we are told of 106 varieties of Pears, sixty of Peaches, fifty-six of Plums, fourteen of Nectarines, twelve of Apricots, eleven of native Grape, twenty of Cherries, three of Quinces, six of Raspberries, four of Currants, fourteen of Strawberries and twelve of Gooseberries—all of them the choicest kinds then known.

The case against the Northern Pacific Railroad, brought by Jacob Austin several years ago, has just been decided in favor of the plaintiff by the United States Supreme Court. The cause of action was for damage to plaintiff's standing timber from a fire set by sparks from an engine. The original complaint alleged \$475 damages, but the testimony developed that more damage than that had been done, and the plaintiff asked leave to amend to \$1,000. The case went to the Supreme Court of Minnesota on the judge's affirmative ruling on this motion. It has since gone to the Supreme Court twice—three times in all—and once to the United States Supreme Court. The latter court gives the plaintiff \$750 damages, together with costs and disbursements. The total verdict is about \$1,100 for Mr. Austin.

Whether or not there are any oospores to be found in the potato-rot, *Phytophthora infestans*, is a question on which opinions are divided. Some of the British botanists accept the views of Worthington Smith, who in 1875 described bodies which he believed to be the oospores, by means of which the rot is able to survive the winter and start up again in the spring. On the other hand, German botanists generally adopted the view that the bodies in question were not the true oospores. The latest contribution on this subject is that of Dr. J. Smorawski in *Landwirthschaftliche Jahrbuecher* of the present year. In cultures of infected potatoes in specially prepared covered vessels he noticed that the mycelium not only produced conidia, but also in places swelled so as to produce oogonia-like bodies. In some cases cells were seen in contact with the oogonia, and Smorawski regards them as antheridia. But in other cases there were no antheridia, and in such cases he thinks it possible that oospores are produced in the oogonia without the action of the male, or, in other words, apogamously, to use the expression adopted by botanists. It must be said, however, that the complete development of the oospores is not figured by Smorawski, and the doubtful point with regard to the existence of oospores in the Potato-rot can hardly be said to be fully settled by Smorawski's observations.

The summer meeting of the American Forestry Association at Quebec last week drew a large attendance, including many delegates from the United States. Lord Stanley came to the meeting and made a very business-like address, as did the principal officers of the Province of Quebec. Lieutenant-Governor Angers gave some very striking figures to show how the forest-wealth of the Dominion had been squandered, while at the same time he made it clear that the Canadian method of leasing the public lands was much more satisfactory than the practice in the United States of selling forest-property outright. The Province of Quebec alone has produced since 1867 ten and a half billion feet of lumber, while the Crown timber dues during the same period had amounted to about ten millions of dollars, and during the last year the revenue from this source alone amounted to nearly a million of dollars. It is no wonder that the authorities of the Dominion are beginning to inquire how long the forests can survive such attacks. No officers were elected at this session; business of this sort will be transacted at a winter meeting which will probably be held in Washington. The discussions, as was very proper, were largely devoted to forest-interests of the Dominion, but excellent papers were read by Professor Lazenby, of Ohio; Colonel Ensign, of Colorado; N. H. Egleston, of Washington; Gen. James Grant Wilson, of New York; H. G. Joly, of Quebec; William Little, of Montreal; M. Vilmorin, of Paris; H. B. Ayres, of Minnesota, and B. E. Fernow. It is our purpose to publish abstracts of some of these papers at an early day.

Preparation for Planting Trees.

THE placing of a young tree in the ground after all preparation for it has been carefully made is the work of a few minutes only. As a rule, the proper season for this operation in latitudes north of this city is in the Spring; but it is a fatal error to delay all preparation until April or May. These preliminary steps require time, and they should be taken with deliberation and care, so that it is not a day too early to make a beginning. In the first place, a careful study of the grounds should be made and the precise spot selected where each tree is to stand. The need for such a study would seem to be self-evident, but, as a matter of fact, the amateur too often waits to purchase his trees until the time for planting has actually arrived, and then he sends for a number of such varieties as he or his friends consider handsome, and after his trees have been delivered on the ground he sets about hunting places to plant them. Of course, in the rush and pressure of spring work everything must be done hastily and carelessly, and too often all the work is worse than wasted.

When the positions have been selected and the proper varieties of trees have been decided upon, it will pay the planter to visit some good nursery and make his own selection from among the growing trees of first-rate and thrifty specimens. He then can make his order intelligently, and he should insist that the trees he has chosen should be lifted from the nursery rows and forwarded to him as soon as possible after the leaves have ripened. Upon their arrival, any bruises which the roots have received should be carefully cut away and the young trees should be heeled in and left till spring. This operation should be performed as thoroughly as the act of final planting. A well drained place well sheltered from the wind should be selected, and fine mellow earth should be sifted among the roots and firmly packed about them. When practicable, a mound should be raised about the stems of the trees, and, if it is beaten smooth, the mice will rarely trouble them during the winter, as they do not like to climb up steep banks under the snow. When the trees are heeled in with care calluses will form where the

roots have been cut and white rootlets will at once be thrown out in the warm earth, and they will furnish a supply of moisture to the trees and prevent their drying out in winter.

By all means the ground where the trees are to be finally placed should be prepared in autumn. This means that a hole should be dug to the depth of three feet, and if the trees are such as grow to a large size there is little danger of making it too spacious. No thrifty tree is in danger of having too much nutriment, and if the hole is five or six yards across no injury will be done. After it has been dug the loam should be shoveled back and the coarse stones picked out, so that in the spring the ground will have become firmly settled. If this work is delayed until planting-time, and a deep hole is then dug, the loose earth will settle away from the roots of the tree and leave air-spaces, which may prove fatal. In the spring small holes should be made in the centre of the large ones, but of ample size to contain all the roots of the tree without bending or cramping. The young trees should then be carefully lifted from their wintering-places, so that the fibrous roots will not be disturbed, and they should be set with all care, as has been often explained in these columns, special pains being taken to have the soil rammed compactly about the roots.

Of course, many trees are successfully planted in autumn; and it is often said that whether spring-planting or autumn-planting is to be preferred depends upon the season. If trees are planted in the fall they should be moved as soon as the leaves have ripened, so that young rootlets will form before the ground freezes. The plan here recommended, however, is safe in any year, and leaves the trees in the best condition to withstand a hard winter or a dry summer. There is nothing novel in the instructions given, and we repeat them now simply because the time is at hand when preparation should begin, and because every year brings a new crop of failures on the part of novices whose delays make success impossible. What is especially insisted on is that every single process in the planting should be done in season and done with care. This means that the planter should be able to give an intelligent reason in every case why a given species or variety has been selected and why it has been placed precisely where it stands. It means that no tree should be planted but a thrifty, well-rooted and carefully lifted individual, and that it should receive no check in transplanting, but continue in uninterrupted growth with every possible provision for, and assurance of, a long and vigorous life. Without such deliberate care every tree planted will be likely to prove a disappointment, which will grow more bitter as the years roll on. While, on the other hand, every tree which is planted as it should be, and which is full of joyous life from the outset, will prove an enduring and ever-increasing source of comfort and satisfaction.

In *Harper's Magazine* for September Mr. Hamilton Gibson's pen and pencil once more invite us out-of-doors to the wild gardens of Nature's own planting. Very beautiful are the pictures of Cypripediums, Lupins, Pyrolas and the rest, and very pleasant are the artist's sympathetic descriptions of these wildings and their ways.

But is it not possible for one to make room in his affections for the flowers of the garden as well as for the flowers of the wood-side and way-side? Mr. Gibson seems to doubt this, and he even stigmatizes as a "pagan marplot" the gardener who had succeeded, as many others have done, in flowering a hybrid Lady's Slipper of his own production.

Of course all hybrid Orchids are not more beautiful than their parents, and some are not beautiful at all. Of course such objects can never have the particular kind of charm which invests a bit of Nature's handiwork chanced upon out-doors. And, of course, a man who devotes himself to hybridizing Orchids or anything else may become so proud of his results as to lose sight of their relative

importance in the vast sum total of flowering plants. But, after all, we cannot have too many beautiful flowers, and many very beautiful ones, which we should not otherwise have had, have been given us by the hybridizer. Moreover, his labors have largely helped the botanist to read the riddles which attend the descent and affinities of wild plants; and, if this is so, it is simply because the hybridizer follows Nature's own lead. Nature herself is the great, persistent and inventive hybridizer, as any one may discover if he will try to study our Oaks, for example, our Willows, or Orchids themselves. If we do well to scorn the gardener who can see no interest in "the wild garden of innocence and peace," are we not equally open to criticism if we find no beauty in the infinitely varied products of the seed-bed and the propagating-house? Could Mr. Gibson have known without the hybridizer's telling which of the *Cypripediums* he saw were man's hybrids and which Nature's? And if not—or even if he could—why might not each challenge admiration on its intrinsic merits?

No doubt it is a degenerate taste which sees no charm in the modest flowers which open trustfully without any care of man, and writers like Mr. Gibson, who invite us to the nooks where they are hiding, are doing a worthy service. But an affectation of simplicity of taste may be as undesirable as other affectations. Cultivated flowers do not lack beauty; many of the flowers of artificially produced hybrids do not lack beauty even when growing in the "degenerate precincts" of the hybridizer's garden.

It is hardly a month ago since we called attention to the danger which threatened the last remaining grove of Giant Sequoias in Tulare County, California, and expressed the desire, which must have been shared by every public-spirited person in the country, that this forest should remain the property of the nation forever. The most that could have been reasonably hoped was that Secretary Noble would withhold this land from entry for a time until public opinion became sufficiently strong to make it possible to secure some protective legislation. But a bill to set apart this grove as a public park forever was at once introduced into the House by General Vandever, and it has already passed both Houses by unanimous consent. The reservation not only includes the particular township first named, but certain other outlying forest-lands, and especially some in which are the fountains of the streams which flow through the principal grove. By this act the park is placed under the exclusive control of the Secretary of the Interior, whose duty it shall be as soon as possible to make and publish rules for its care and management. It is enacted that these regulations shall provide for the preservation from injury of all timber, mineral deposits and natural curiosities within said park, that the reservation shall be maintained in its natural condition, and, also, that the fish and game within its boundaries shall be protected from capture or destruction for the purpose of merchandise or profit. Provision is made for the erection of such buildings as may be needed to accommodate visitors upon leases not exceeding ten years of parcels of ground not to exceed five acres.

The proper management of this reservation, however, is a matter of future concern. The cause for congratulation is that there is now no danger that this last remnant of the race of colossal trees shall be given over to destruction. And now, why should not a similar reservation of Redwood forest be made somewhere in the Coast Range? These trees are even more beautiful and almost as interesting as the Big Trees, their relatives. Redwood timber is of such well known value that it is rapidly falling before the axe. In a few years these beautiful forests will be only a memory. It may be that there is no typical Redwood forest still remaining in the hands of the Government. If so, the state of California or some of the wealthy citizens of that state could leave to posterity no more enduring monument of their public spirit than the gift of a

tract of Redwood timber with provision for its protection forever.

And have we not reason to hope that the Committees of Public Lands in both Houses, to whose efficient action the country is primarily indebted for the salvation of the Sequoia grove, may now be encouraged to report the Yosemite Park Bill? The success of the Tulare Reservation Act would seem to indicate that the sentiment of Congress in reference to matters of this sort is now altogether wholesome. The Yosemite bill can be passed at this session if the effort is only made with courage and confidence.

Plan for a Small Town Place.

IN GARDEN AND FOREST for May 28th, 1890, we published outline plans of four small places, showing the importance of a skillful disposition of the house and other buildings, with reference to special local circumstances. We present this week one of these same plans on a larger scale with the intention of showing the design a little more fully.

The place is not a new one, for the house, which is an old-fashioned, square, colonial brick structure, was built about fifty years ago, and the garden was laid out and planted at the same time. It had been long neglected and trees allowed to grow up and crowd each other so much that many were ruined, and they were so spread over the ground as to destroy all breadth. A few years ago, while alterations and additions were being made to the house, it was thought best to rearrange the garden at the same time, and, of course, the first thing to do was to thin out the trees and save the best of them, leaving in general a belt about the borders of the property to screen out neighboring buildings.

A low, broad terrace was thrown out on the east side of the house, lending dignity and support to it, and a wall was carried from the house to the street on the south, which completely enclosed the garden and made it retired, domestic and secluded.

As the house was distinctly a winter residence, this seclusion and protection of the garden was considered the more important, and for the same reason there were planted on each side of the circuit walk and about the borders of the property groups and masses of broad-leaved evergreen shrubs, mostly *Rhododendrons*, but also such plants as *Andromedas*, *Kalmias*, *Mahonias*, *Daphne*, *Ledum*, etc., to get variety and to gracefully edge down the masses.

It will be noticed that the house has two entrances: one from the street on the south, and the other from the paved court-yard on the north. This court serves also as an entrance to the stables and to the kitchens, which are in the "L" of the house, but so arranged as not to be obtrusive or disagreeable from the court.

The place is about two acres in extent, and is situated on flat, high ground in one of the larger cities of New England.

Color Notes on California Wild Flowers.—II.

ONE of the prettiest of the California wild flowers in June and July is the Chilian Canchalagua (*Erythraea venusta*). It is abundant in southern California on the mesas and hill-sides, and in the valleys, usually less than a foot in height, but in some moist localities exceeding two feet. The rotate corolla, with a slender tube and five (rarely four or six) divisions, exceeds an inch across, the divisions brilliantly colored, of a shade belonging somewhere between solferino and magenta, too dark for rose-purple, with a narrow white circle in the centre. The centre and the tube of the corolla, together with the rather prominent stigma, are of a greenish sulphur-yellow, the style and filaments white, while the prominent, exerted, erect anthers are of a brilliant lemon-yellow. The blossoms close their eyes upon the going down of the sun, turning their bright, dewy faces to him again in the morning. The flowers will remain bright and fresh for days and weeks after they are gathered without being put in water. This is one of its most excellent features, the value of which will be recognized by florists. Sometimes, though rarely, the divisions of the corolla are of a delicate pale lavender and often pure white in this species. The white ones are especially lovely when seen in a mass of the brilliant solferino. It will doubtless prove easy of cultivation, and if so, the California Centaury will become deservedly popular in American gardens. Medicinally the plant possesses valuable antiseptic and febrifuge properties, and is in high repute as a bitter tonic and stomachic.

Agave Desertii, one of the Mescal or Maguey plants, so abundant on the western borders of the Colorado Desert, produces

a stalk about seven to ten feet in height, surmounted with a large panicle of flowers of a chrome-yellow. The foliage is of a glaucous green.

Krameria canescens, also a denizen of the Desert wilds, is a low shrub about two feet high, bearing in spring-time a profusion of showy magenta colored flowers.

Læselia tenuifolia is a showy plant, of a span to a foot in height, which produces an abundance of flowers of a color somewhat difficult to describe—something between a poppy-red and a carmine, and very brilliant. This is related to the Phloxes and Gilias, and is equally worthy of cultivation as any of them. It is found abundant on the table-lands bordering the Colorado Desert on the west, in Lower California, and a few plants stray north of the boundary into this county. The altitude of its habitat is from four to six thousand feet. This herb is also credited with valuable medicinal properties, being held in high repute by the Indians and Mexicans, who use it in various diseases, especially in fevers.

In the mountains of Southern and Lower California there is a peculiarly beautiful form of *Calochortus luteus*, with flowers an inch and a half across of deep lemon-yellow, with a maroon-purple spot near the base of the petals. The glandular area is also of a maroon-purple, the space between being occupied with numerous lemon-yellow hairs. The scape is one to two feet in height. The plant is rare, growing very scattering in rocky places.

Mimulus brevipes has large, showy lemon-yellow flowers, and is one of our most abundant annuals.

Mimulus glutinosus is a shrub rarely more than two feet high, and produces in spring an immense mass of large buff-yellow flowers an inch and a half long, over an inch across, with two orange spots in the centre of the flower, the tube of the corolla white.

Dicentra chrysantha is a fine perennial plant, with delicate glaucous green, finely divided foliage, and producing a tall spike of flowers of a bright gamboge-yellow. It is not especially showy, but quite noticeable, and has long been in cultivation in Europe, where it is still in good demand. Like many others of our California wild flowers that have met with success in Europe, it still seems to remain unrecognized in eastern America.

Chanactis artemisæfolia is a rank growing, rather conspicuous and pretty annual with us, attaining a height of three or four feet, with wide-spreading branches, bearing numerous white composite flowers in balls an inch in diameter.

Sphæralcea Emoryi is a half-shrubby plant, one to five feet high, closely related to the Abutilons, with foliage of a sage-green, and showy, flame-scarlet flowers. It is easily cultivated and a very desirable plant.

Thamnosma montanum is a low shrub found on the mountains bounding the Colorado Desert on the west. It has a very pungent, spicy odor. The yellowish bark of the nearly leafless plant is prettily set off by the numerous prune-purple flowers, which fade to white.

Astragalus Purshii, var. (?) *coccineus*, Parry (West American Scientist, vi., 9-10), is one of the most beautiful and showy of the genus, producing a profusion of handsome scarlet flowers. It is confined to the same region as the last, and is probably the last plant to receive its name at the hands of the late Dr. C. C. Parry. It is scarcely a span high, the stems and foliage covered with a dense white tomentum, and forming a rather broad, compact mass, which wonderfully enlivens the rocky or sandy places where it grows with its large and showy flowers. It is the most worthy species of the genus in Southern California for extended cultivation.

Monardella lanceolata is a showy annual of our mountains, producing masses of bright Phlox-purple flowers. It is six inches to a foot high, branching, with a strong but pleasant Pennyroyal perfume, and is well worthy of cultivation.

Orcutt, California.

C. R. Orcutt.

A Suggestion from Nature.

OBSERVING planters can often find instructive hints as to the arrangement of trees and shrubs by studying the ways in which they naturally group themselves in certain soils and exposures. Before our camp to-day lies a small island, which may be taken as the type of very many similar ones in the "park region" of Minnesota, and any landscape-gardener who has a little island to cover with foliage could gather some fresh ideas for his work by taking note how Nature has done hers.

The beach of the island is sand on clay. The interior rises some ten feet above the water and is gravelly. In the shallow water are Bullrushes; dense near the shore, and the shore itself is bordered with a circle of pale Willow-bushes. Inside

the Willows is a circle of Alders, a little taller; then a circle of Birches, with occasional dark spires of Fir; then Elms, with a central dome of Norway Pine.

Other islands of the type, but smaller, have circles of Spiræa, Willow and Maple, with a group of Elms or a single drooping Elm forming the dome. Some have a single White Pine in the centre; some a group of Firs or a White Spruce.

It should be borne in mind that Fir, Spruce and White Pine require damp subsoil, and in nature are brushy underneath, while the Norway Pine grows best on dry ground, and as soon as a roof is formed the lower branches drop off and a yellow carpet of the leaves is spread underneath.

Caribou Lake, Minn.

H. B. Ayres.

A New Enemy to Willows.

EARLY in the present year I called attention to the imported Elm-borer (*Zeuzera pyrina*), which is now known to extend from New York City to beyond Newark, as a danger to our Elm. The present season has brought into notice, as a danger to Willows, another imported insect, this time a beetle, known as *Cryptorhynchus Lapathi*. It is one of the snout beetles of which the white Pine weevil is a shining example, and the injury to Willow is in appearance much like the injury to Pine. The beetle is black in general color, about five-sixteenths of an inch long and nearly half as wide, with the ends of the wing-covers a rich pale pink, an oblique shoulder stripe of the same color and the thorax also with pinkish lines above. There are five tufts of elevated black scales on the thorax and a linear series on each wing-cover, which are quite prominent and readily identify the insect. Altogether it is rather a pretty species, the legs being also banded with pink. The beetle makes its appearance in June and July, and lays its eggs in the branches, and, sometimes, also the stems of young Willows, apparently very close together. The larvæ hatch the same fall, burrow into the wood until the branches are honeycombed in every direction and change to a pupa in May or June. Samples of infested branches shown me contain burrows as closely run as the wood will sustain, and in the neighborhood of Newark, I am informed, many Willow clumps have been entirely killed off.

The first notice of this species in America was by Mr. Wm. Jülich, of New York, who in 1887 published the appearance of the species near Hoboken, New Jersey, in Willows there, and mentioned that isolated specimens had been found previously in Hoboken and on Staten Island. Since that time it has been found more frequently, and in the summer of 1889 a single specimen was taken near Newark, where previously none had been found. Early in 1890 the Newark collectors noticed the dying Willows and bred numerous specimens of the beetle from infested branches. In Staten Island it has also increased and multiplied and bids fair to become a serious pest. In Europe the species is a Poplar feeder, and probably this tree will not be exempt here when the insect is thoroughly domesticated.

There is only one treatment possible for this pest, and that is cutting all infested branches and burning them to prevent the maturing of the beetles. The cutting should be done early in spring, when the infested branches are most easily recognizable, and the remedy should be thoroughly applied. A tree once attacked will be eventually killed if the beetles are allowed to breed freely or if the knife is not thoroughly used. It is a small measure of comfort to know that the insect has brought with it a parasite which may eventually succeed in obtaining control; but at all events we seem to have fairly domesticated with us another emigrant which may prove as serious a pest as the Elm-leaf beetle.

Rutgers College.

John B. Smith.

Buildings should not stand alone in open ground, lest they have the effect of spots, and appear foreign to the nature around them and not as if they grew in it. It is in the highest degree important that they should be in keeping with the landscape. Buildings within a park are only parts of a whole; and they must be designed with just as much regard to the view of them as to the view from them. A certain irregularity in park buildings is to be desired, as more conformable with nature and more picturesque. Buildings half hidden behind each other, large and small windows in the same wall, door-ways unsymmetrically placed, projecting and retreating angles, now and then a high bare wall with a rich cornice, isolated towers, widely overhanging roofs and balconies unsymmetrically set; in short, everywhere a striking but far from in-harmonious irregularity, which expresses imagination, while yet the motive for every departure from regularity either appears at once, or may be divined.—From *Pückler-Muskau's "Andeutungen über Landschafts-gärtnerei,"* 1834.

New or Little Known Plants.

A Curious Form of *Kalmia*.

THE monstrous form of Laurel (*Kalmia latifolia*), figured on page 453 of this issue, was discovered a few years ago by Miss M. Bryant in a large natural Laurel-thicket near Deerfield in Massachusetts. The attention of the public was called to it by Dr. Asa Gray, to whom Miss Bryant submitted specimens, and who published in the *American Naturalist* (iv, 373) an account of this freak of nature in a note entitled "Dialysis with Staminody in *Kalmia latifolia*."

The monstrosity consists in the division of the ordinarily five-lobed, saucer-shaped corolla into five narrowly linear or sometimes nearly thread-shaped petals alternate with the calyx-lobes. They are ovate at the base and by the revolution of the margins become sometimes almost thread-shaped above and so resemble filaments, the resemblance being increased by the fact that these petals are occasionally tipped by a single abortive anther. The plant, therefore, serves as a capital illustration of one form of dialysis and possesses considerable interest to morphologists. The pouches on the inner surface of the corolla peculiar to *Kalmia*, which receive the anthers before the flower-bud expands and hold them back, until freed by insects visiting the flower, thus insuring cross-fertilization, are rudimentary in this abnormal variety and are represented by a slight depression on the inner surface and a corresponding boss on the outer surface of the petals. The stamens are normal except that they are erect or at length somewhat recurved with anthers entirely free. The pistil is normal and the plants produce seed freely in cultivation.

One of the two or three plants discovered by Miss Bryant was introduced into the Arnold Arboretum, where it flowers regularly every year and produced the specimen from which Mr. Faxon has made the drawing which re-appears in our illustration.

The casual observer seeing the plant in flower would never guess that it was a *Kalmia*. The flower certainly is not as beautiful as that of the normal *Kalmia*, one of the most beautiful of all flowering plants. They are very attractive, however, both before and after expansion. This plant, which flowers very freely, is well worth cultivation, therefore, not only as a curiosity, but as an ornament to the garden. It can be propagated by grafting on the normal form of the *Kalmia*.

Foreign Correspondence.

London Letter.

PROTECTION FOR THE ORIGINATORS OF NEW PLANTS.—This was the subject of discussion in *The Garden* and other London papers two years ago. Mr. T. Francis Rivers, whose fame as a raiser of new fruits of sterling worth is world wide, started the discussion by stating a very strong case in favor of protection, and suggested that a reasonable time should be allowed for the raiser to keep a right of property in his invention. When Mr. Rivers complains that seedling fruits raised by him and recognized as being worth planting for industrial purposes have yielded only a very unsatisfactory return, we are bound in fairness to ask if this kind of thing cannot be remedied. Difficulties of a serious kind were pointed out in the discussion which followed Mr. Rivers' letter, and these are emphasized in the leader in *GARDEN AND FOREST* for July 30th. The weight of opinion is, on the whole, against protection. Abuses which would prove probably far more intolerable than unfairness to the raisers of new plants would be the inevitable result of any attempt to protect the latter. In the case of new plants introduced from some other country, protection would rarely be of much avail, unless the introduction of the same plant by any one except the holder of the copyright were forbidden. The temptation to use the name of a valuable new plant for a counterfeit would, as you suggest, be strong, but on the theory that the Rose by any other name would smell as sweet, a copyright plant with a non-copyright name would soon find a market if deserving of it.

After all, the give and take principle must be fairly satisfac-

tory to dealers in new plants. If Mr. Rivers finds that his new Plums are a source of considerable profit to many who have speculated in them, he can, on his part, do likewise with the new Grapes or new Apples raised by somebody else. From the point of view of the consumer it must be an advantage to have, let us say, a thousand propagators scattered all over the world diligently working up as rapidly as possible a stock of a new and improved fruit or vegetable or flower rather than to be compelled to wait until the copyright had ceased. That the bulk of growers would wait rather than pay a high price is shown by what is done in the case of those articles where protection is afforded. That the nation, as a whole, is a gainer where there is no protection is a political belief which I think applies in this matter of plant distribution.

SCHUBERTIA GRANDIFLORA, so well figured in *GARDEN AND FOREST*, page 368, is a most useful summer-flowering climber, as it grows and blooms freely under the most ordinary treatment. In the stove it is trained along a rafter, which it completely hides with healthy green leaves and numerous clusters of ivory-white, Stephanotis-like flowers; in the same house it forms a good specimen plant when the shoots are trained over a balloon-shaped trellis. In addition to these uses we have it trained along the roof of a greenhouse, where it has flowered well all summer. Evidently this plant is as accommodating in its requirements as its near ally, *Physianthus albens*, which also may be used either in the greenhouse or stove. Cuttings of the *Schubertia* have not readily struck root here, but seeds have been ripened from which a stock of young plants have been raised. *Physianthus albens* also fruits freely here.

BEGONIA HAAGEANA is a most ornamental flowering plant for the stove. It grows to a height of about three feet, has large, handsome foliage, and produces all summer numerous broad, semi-drooping racemes of large pale flesh-colored flowers. It was introduced from Brazil by Messrs. Haage & Schmidt three years ago, and was figured in the *Botanical Magazine*, t. 7028, as *B. Scharffiana*. Several large specimens of it are now the most attractive of all the evergreen Begonias in the Kew collection.

IXORA MACROTHYRSA is this year again very fine at Kew. The heads of flowers are as massive as the largest heads of *Hydrangea hortensis*, and they remain fresh almost as long. Their color is a deep crimson.

PASSIFLORA KERMESINA (Raddiana) is a very effective climber in the stove; and it is as easy to cultivate as the commonest of Passion-flowers. For small houses it is particularly useful, as it requires only a square yard or so of space to make a good display of bloom. Trained loosely along a rafter so that the shoots may hang downward when clothed with its pretty carmine flowers it produces a pretty effect. The leaves are medium in size, three-lobed, and colored dark green above, deep claret below. The species is a native of Brazil, whence it was introduced into England sixty years ago. *P. Loudoni* is a cross between it and *P. racemosa* (princeps), and *P. Kewensis* between it and *P. cœrulea*.

CATTELEYA HARDYANA is perhaps the most gorgeous colored of all Cattleyas, as is indicated by its being supposed a wild hybrid from the very fine species *C. aurea* and *C. gigas*. It is imported with *C. gigas*, which it resembles exactly in pseudobulbs and foliage, so that a newly imported *C. gigas* may possibly prove on flowering the much coveted *C. Hardyana*. Recently this plant has attracted a good deal of attention. It appears to have one bad fault, namely, the liability to fall a prey to that mysterious disease which too often attacks and suddenly destroys *C. Dowiana*. Plants of *C. Hardyana* are sometimes shown at the meetings of the Royal Horticultural Society, where they are always much admired. There were several at the meeting held this week, and along with them a very similar Cattleya called *C. Massaiana*. This is said to be a natural hybrid from the same parents as *C. Hardyana*, and whatever their origin the two are certainly very much alike. The former has the sepals and petals colored a pale rosy salmon and a large lip fully three inches across, shaped as in *C. Dowiana*, its color being rich maroon-crimson in front, with a pair of broad patches of yellow and veins of the same color running into the throat. The plant worthily obtained a first-class Certificate. Plants of ordinary *C. Dowiana* have been sold for this beautiful Cattleya. Flowering at this time of the year these plants are particularly useful. I might mention that there is a tendency amongst Orchid fanciers to call all deep colored varieties of *C. gigas* forms of *C. Hardyana*. The former is a magnificent Orchid, but it lacks the beautiful gold penciling on the lip, so conspicuous a character in true *C. Hardyana*.

DAHLIAS.—There were some good flowers of these exhibited at the last meeting of the Royal Horticultural Society, chiefly

from the nursery of Messrs. J. Cheal & Sons, Sussex, whose collection of Dahlias is a choice one. The most striking of the new kinds was a Cactus variety called Mrs. J. Douglas, the flowers large, of the Juarezii type, the petals curled and colored salmon, tinged and shaded with purple. Although not bright in color, it is a new shade in show Dahlias. Among single-

cerise; Primrose, one of the prettiest of yellows. Besides the Cactus kind called Mrs. J. Douglas, I noted the following as first-rate in color and form: Beauty of Brentwood, rich purple; Yellow Juarezii, clear canary yellow; Cochineal, rich crimson, with Juarezii itself, which is still unbeaten as a bright crimson. Amongst Pompone varieties I selected: Admiration, crimson

Fig. 56.—*Kalmia latifolia*, var.—See page 452.

flowered kinds the best shown were: Gulielma, pure white, margined with buff-yellow, a very pretty flower; Victoria, white, with a deep crimson margin; W. C. Harvey, flowers large and colored rich yellow, with an orange shade; Brutus, a rich crimson; Duchess of Westminster, white and elegant as an Anemone; Mrs. Cleveland, a clear terra-cotta, shaded with

with white tips; Don Juan, rich maroon; Golden Gem, bright sulphur yellow, and Hector, scarlet. These small flowered varieties are useful for supplying cut-flowers for the house. To produce effect in borders or beds the colors ought to be bright and clear, the dull colors being much less telling.

Notes on Shrubs.

A LATE-FLOWERING LILAC.—On page 165 of the present volume of GARDEN AND FOREST there is given an illustration from a photograph of a cluster of the blossoms of *Syringa Pekinensis*. Although the production of a second or late crop of flowers is a circumstance not unusual among some kinds of shrubs, it seems worthy of note that a plant of this species is now (September 9th) blooming freely at the Arnold Arboretum. The plant is upright in habit and about fourteen feet in height. It bore no flowers in June, which is the regular blossoming season of other individuals of the species. There are from twenty-five to thirty large panicles of flowers on the plant, the largest clusters being about a foot in length. Unlike their usual habit, these panicles do not all open their flowers almost simultaneously, only a few panicles being in blossom at any one time. The earliest of these were showy in the last week of August, and with cool weather the latest will not fully develop their bloom until the last week of September at least. The panicles are borne at the tips of this season's shoots. Some of them, as before stated, are a foot in length, and they average quite as large and fine, and are as fragrant, as any produced in the usual flowering season. Usually the second or late blooming of a plant is much inferior to the first. At a distance the great panicles of flowers of this *Syringa* might be mistaken for those of *Hydrangea paniculata grandiflora*, which is just now in its best condition. It seems too much to expect that the late flowering of this specimen of *S. Pekinensis* will prove to be a constant habit; but if it proved so it would be worth perpetuating, and would be a valuable acquisition among the late white-flowered shrubs which attain large size. Other plants of *S. Pekinensis* which flowered at the regular season, in the latter part of June, are producing an abundance of fruit.

BERCHEMIA RACEMOSA, a Chinese and Japanese plant, belonging to the Buckthorn family, opens its earliest flowers here during the last days of August. The rather large compound panicles of small greenish white flowers are borne on the ends of the shoots or lateral branches, and, although noticeable against the general mass of dark green foliage, they are not very attractive or showy. In this climate the chief claim to ornamental value of this plant is in its clean, smooth, dark green foliage, which forms a good covering to the stems. The leaves are ovate, usually somewhat pointed, and are from one to two inches long. The blossoms are not even so large as those of the common Buckthorn. The fruit has not been produced here. It is oblong, about the size of small peas, and is said to be quite showy and ornamental. The late flowering habit would prevent the fruit from maturing here before the early autumn frosts occurred. This species has not so far proved as hardy as could be desired, although there are probably some situations in this latitude where it might attain a fine size and development; and where, when it became old and well established, it would withstand the vicissitudes of our climate. It is a trailing or twining shrub or vine, having apparently more of the habit of the Bittersweets (*Celastrus scandens* and the Japanese *C. punctatus*) than any others of the familiar shrubs or vines of our gardens.

Under favorable conditions the stems would probably climb high into trees or other supports, but here they only attain a length of ten or twelve feet at the most, although they are very free growing.

The American representative of this species, the Supple Jack (*B. volubilis*) of the southern states, is hardly so well able to endure our winters as *B. racemosa*.

Arnold Arboretum.

J. G. F.

Mulching.

THERE is really no tree or plant which is not benefited by mulching. It is not improbable that we shall yet come to a system of agriculture in which mulch will be used for Corn and Potatoes and garden vegetables. Experiments in that line have proved beneficial. The only question is, Will the expense and trouble be compensated by sufficiently larger crops? Taking into consideration the liability to droughts there is little doubt but we can devise methods of mulching that will pay. What we need now is statistics of losses and waste of our fairly estimated crops. We must then consider how much of this is preventable. I believe that the loss and waste of the fruit crop is at least one-half, and of the Corn and root crop one-fourth of the average. The fluctuation of prices is not the chief difficulty with the farmer; the point to aim at is securing

full remuneration for work and expense by getting invariable harvestings.

But mulching has an application of very great importance in the planting of trees. No tree, under any circumstances, should be set without a foot covering at once. It is the one most important point in planting, more so than large holes and carefully set roots well pounded down. Pruning has less to do with the life and growth of the tree. I reckon that a Pear-tree well mulched gains three years over one that is not. Chip refuse, coal ashes, wood ashes mixed with waste, long manure, cut straw, old or waste hay, are all good material. Whoever has evergreens or an evergreen-hedge to set will find three-fourths of his success dependent on mulching, the other fourth on not letting the roots see the sun or get dried for one moment. I moved a hedge of twenty years' growth six years ago and did not lose one plant. It was well done in all respects, but I relied mainly on puddling and mulching.

We have yet to learn the value of mulch in the handling of flowers. Setting out bedding plants involves a loss and a set-back; but if mulched with a handful or two of coarse compost the loss is reduced to a minimum. In the western states gardening and orcharding require more attention to root protection than in the Atlantic states; but it is important even in the most moist sections. The secret of success with trees and shrubs is persistent mulching.

Clinton, N. Y.

E. P. Powell.

Hollyhocks.

IN British gardens of all sorts and sizes the Hollyhock is a favorite plant, and its admirers and growers are by no means few. Taking it for granted that the same may be said of the Hollyhock in America, the following remarks, culled chiefly from a lecture recently delivered before the Royal Horticultural Society in London by Mr. James Douglas, may be of interest, and even of value, to American growers.

The Hollyhock, botanically known as *Althæa rosea*, is a very old inhabitant of English gardens, single and double varieties of it having been recorded as far back as the year 1597. Its introduction, however, according to Dr. Masters, was probably much earlier than this, and it is possible that it first appeared in the time of the Crusaders, who brought it from Asia Minor and the Levant. Gerard, who was born in 1545, mentions single white, red and purple varieties, and also double purple and scarlet forms, as growing in his garden; and Parkinson, who flourished a quarter of a century later, enumerates a much larger number of varieties, thus showing that the work of raising seedlings had been carried on to a great extent in the meantime. Since this period much progress had been made, and numerous varieties created, and a most remarkable thing was that many of the additions were owing to cottagers who had to work at their particular businesses from six in the morning till the same hour, and often even later, at night, but who, nevertheless, found time to look after their Hollyhocks and grow them to such perfection as to almost make a professional gardener envy their success.

The propagation of the Hollyhock is most easily accomplished by sowing the seed in the open border about May. When the plants are large enough to be easily handled they may be pricked out in the place where it is intended to flower them, in rows, about three feet apart, and four feet between each row. There are, however, other methods of propagating the Hollyhock, and one is by cutting off a leaf adhering to a portion of the stem, and containing an "eye" in the axil, and thus making cuttings, which will readily strike in a hot-bed. Another means is taking the shoots from the base, while root-grafting is also adopted to propagate the plants, a shoot being cut so as to fit into a corresponding cut in the root, and then securely tied round with matting.

The soil for Hollyhocks should be prepared early in autumn for the next year's crop, and should be made deep and rich. When the plants are placed in positions in spring they should be staked at once, so as to avoid disturbing them at a later period. When well established little attention is necessary, but if the best results are desired the plants should be regularly syringed with clean water. Directly any flowers begin to decay the petals should be at once removed, as, if allowed to remain and become mildewed, the seed-pods are apt to become affected and rot. The flowering and seeding period having come to a finish, the stems may be cut down to within six inches of the ground, after which the stocks may be dug up and plunged in a somewhat dry material, such as cocoanut fibre, there to rest for the winter. In the spring, all the shoots, except one, which spring from the old stock may be taken off for cuttings, and will soon strike in a hot-bed or frame.

As to the enemies of the Hollyhock the only insect which does much damage is red spider. An experienced gardener at once recognizes the presence of this pest by the leaves assuming a yellowish appearance. The best way to combat it is by washing the leaves thoroughly with a weak solution of soft soap. The Fungus known as *Puccinia Malvacearum* is a tiresome disease which attacks the Hollyhock at all stages of its growth. Mr. Douglas, however, found that when he left his plants standing out for two successive winters they were quite free from this fungoid disease, whereas afterward,

only, which he thinks is far superior to such abominable mixtures as soot, soap and sulphur. Mr. Smith, a large grower of Hollyhocks, never grows his plants under any circumstances beneath glass, believing it to be a forerunner of the Fungus disease. His seeds are sown in the open air, and his cuttings are put into open borders, which, however, have a southern aspect. Should disease make its appearance at any time, and, indeed, to prevent its appearance at all, a mixture composed of one peck of soot, two pounds soft soap and one pound of flour of sulphur is used. The mixture is made in a

Fig. 57.—Plan for a Small Town Place.—See page 450.

when placed in a cold frame for the winter, the disease attacked the young shoots again in the following spring. It was combatted by taking off the affected leaves and painting the remainder with a solution of soft soap and sulphur. The inference to be drawn from this experiment is that if the plants are grown out-of-doors entirely they are free from the attacks of *Puccinia*. Recently Condry's fluid has been said to be one of the best destroyers of the disease, which it completely withers without in the least injuring the leaves of the Hollyhock, and Dr. Masters has great faith in sulphate of copper

zinc pail with hot, but not boiling, water, and thoroughly well stirred. It is afterward strained through a canvas screen so as to enable it to be readily taken up by the syringe. Every day as soon as the buds begin to appear the plants are well syringed with the solution until the flowers open, and no sign of disease or thrips ever appears. Another disease hitherto not mentioned is known as the "white mildew." This appears during hot summers, attacking the stems, and in a few hours causing the leaves to droop and the flowers to become flabby. The only remedy for this white mildew is to cut off the stem

and burn it at once, otherwise the disease is liable to extend rapidly to other plants.

It is the same with Hollyhocks, however, as with other classes of plants—some can grow them with little trouble, while others, with the greatest care, cannot succeed so well as many cottagers. This was the experience of Mr. Cannell, of Swanley, who always found the disease get the best of him when he used to grow a quarter of an acre of Hollyhocks. He had tried all sorts of remedies, but failed.

London.

Phono.

Sarracenias.

THE native Pitcher Plants, or "Side-saddle Flowers," as they are sometimes termed, are among the most interesting of bog-plants, and, when well treated, their curious foliage and quaint flowers give a pleasing variety in the arrangement of a cool house or conservatory. In general, they are not specially difficult to manage when under cultivation, the northern species, *Sarracenia purpurea*, of course, being perfectly hardy, while the various species belonging to the southern states will flourish in a temperature of about fifty degrees. The soil best suited to their needs is a mixture similar in character to that in which they are found in a wild state, this being usually composed of peat and living sphagnum, though under cultivation it is advisable that a liberal quantity of drainage material be placed in the pots or pans in which the plants are grown. In further imitation of nature a covering of live sphagnum may be placed on the surface of the soil, as this is not only an addition to the appearance, but also of benefit to the plants. An abundance of water during the growing season is, of course, necessary for the Sarracenias, and while as much is not needed during the winter, yet they should never be allowed to become actually dry. Some shade should be given all through the summer, and also free ventilation, for when kept too close and warm these plants are subject to the attacks of thrips, by which the foliage is soon disfigured. Enough variety can be found among the types to form the nucleus of a most interesting collection, to which may afterward be added some of the many fine hybrids obtained during late years.

Among the best of the typical species may be classed *S. flava*, one of the strongest growers, and producing its erect, funnel-shaped leaves or pitchers in profusion, some of the latter attaining a height of fully three feet. The pitchers of *S. flava* are bright green in color, while the flowers are light yellow or yellowish green, as the flowers differ somewhat in shade on different specimens.

S. Drummondii is another fine species of strong growth. A good specimen throws up its leaves to a height of three feet. These are also bright green in ground color, with the addition that the veining of the upper part of the pitchers is marked out in crimson, and the flowers are also dark crimson. This makes the plant entirely distinct from *S. flava*.

S. Drummondii alba is a most effective variety of the preceding, and is similar to the type in general characteristics, but distinguished from it in having the upper portion of the pitchers beautifully variegated with white. This is, doubtless, the best of the native varieties, and makes a fine specimen for exhibition purposes.

S. rubra is also a pretty species, though not quite as strong a grower as the sorts already noted. The pitchers are somewhat smaller and more slender in form, and they are veined and their upper portion frequently flushed with dull red. The flowers are quite dark in color and pleasantly scented.

S. variolaris is an odd-looking species, and has erect, hooded pitchers, winged in front and more or less marked with white. This plant bears a closer resemblance to the Californian representative of the Sarracenia family (*Darlingtonia Californica*) than any other species with which I am familiar, but it differs from the latter in having the true Sarracenia flower.

S. psittacina has some points in common with *S. variolaris*, chiefly in the shape of the pitcher, but *S. psittacina*, being prostrate in habit and much smaller in all its parts, is thus made abundantly distinct from it. To render it effective, *S. psittacina* should be massed in a large pan, and, for that matter, this is the most satisfactory way to grow any of the species, and with a little care they will make worthy ornaments for any conservatory.

The hardy pitcher plant, *S. purpurea*, may also be grown as a greenhouse plant, but under such conditions it seldom attains the rich reddish purple tint that is so admirable in the plant when growing in its native swamp, and it is, therefore, best that this species should be reserved for a snug corner in the bog-garden.

Holmesburg, Pa.

W. H. Taplin.

Notes on American Plants.

ONE of the most interesting plants at this season of the year, on account of its fruit, is the White Baneberry (*Actæa alba*). The oblong racemes of white flowers, which come about the middle or last of May, are quite pretty, but at that season are not so valuable because so many other plants are in flower. But now its large, shiny, white berries, tipped with black, take the place of the flowers, and remain prominent a long time. It has the advantage of many other plants of this sort, for there is nothing to take its fruit. Birds never seem to eat the berries, and they are not inclined to drop off as soon as mature, as many others do. Its height varies from one to three feet, and it is not rare to see plants well fruited that are scarcely ten inches high. It likes the shade, a rich and well drained soil, and may be transplanted in either spring or autumn.

Zephyranthes candida, a fine representative of the Amaryllis family, was sent us from southern Texas. It comes from a medium-sized spherical bulb, which is covered with a thin coating not very unlike that of an onion. It seems to be a strong, healthy species, with numerous grass-like leaves a third of an inch or more in width. The large white flowers come later in the season than most of its class, which makes it the more valuable. They are nearly two inches wide and single at the summit of the almost naked scape. It is useful for cutting, though the stalks are not so long as those of the Cooperias. We have not tested its hardiness, but I suppose it would not stand much frost, and it is not necessary that it should, for these bulbs from southern Texas and Mexico winter very nicely in the cellar and are among the easiest of tender plants to manage.

Gentiana linearis, which was formerly known as *G. saponaria*, var. *linearis*, has a closed flower, usually over an inch long, of a light blue color. Its leaves are long and narrow, and the numerous simple stalks are from one to two feet high. Near the summit of the stronger ones are borne two to four light blue flowers. It blooms considerably earlier in the season than the common closed Gentian (*G. Andrewsii*), and its habitat is confined, I think, to peat bogs in partly shaded situations. Transplanted into light loamy soil in the shade it does finely, especially after it becomes established. It may not always flower the first year after transplanting, but if it is in a suitable location it will the second year, and will continue to thrive for a long time thereafter. It may be transplanted in spring or early autumn.

The common closed Gentian (*G. Andrewsii*) is already in many collections of our native wild flowers. It is a valuable hardy perennial, not difficult to manage, and does fairly well in either sun or shade, though shade seems to suit it best. A moist loamy or gravelly soil seems to suit. It may not always live, but there is seldom any trouble in its management. It is a more leafy and stocky plant than the former, of about the same height, but with shorter and wider leaves, and shorter and thicker, somewhat darker blue flowers. It likes a moist soil, but not too wet. It transplants well in either spring or autumn.

Aster acuminatus is a species which grows in cool mountain woods. Most plants of this species are not very showy, but in some favorable locations they bear an abundance of large light purplish flowers in wide, flat heads, and are very handsome. This Aster is usually only a foot or fifteen inches high, and in some of the finest specimens the flat heads or corymbs of flowers are nearly six inches wide. It soon forms dense beds, and if the soil is very rich and moist it may become almost a pest. It needs more time to become established than most species, and a partly shaded location is better than a sunny one.

Southwick, Mass.

F. H. Horsford.

Dendrobium Findlayanum.—This is a very fine species and one easy to manage. The flowers, which, if spread out, would measure from three to four inches across from tip to tip of the petals, are produced from the upper portion of the stems, either singly or in pairs, on pale pink pedicels. The usual time for their appearance is about March and April, but it frequently happens that plants of *D. Findlayanum* will be found blooming as late in the season as July and August. The sepals and petals are pure white, with a purple stain at the tips; the former are oblong-lanceolate, and the latter oblong-elliptic, much broader and having a wavy margin. Comparatively speaking, the lip is large and roundish, the concave portion being deep orange-yellow, outside of which is a band of white decorated in front with a conspicuous stain of purple. To complete the description of the entire plant, the stems or pseudo-bulbs, which attain a height of twelve to eighteen inches, are remarkable for having each joint swollen into a pear-shaped or obovoid body, the attenuated base of which is

clasped by the sheath of an oblong-lanceolate acute leaf about three inches long and somewhat leathery in texture.

D. Findlayanum takes its name from a Mr. James Findlay who seems to have been the first European to discover it, about 1867, on the mountains dividing Burmah from Siam. Mr. Findlay called the attention of the veteran collector and botanist of Moulmein—Rev. C. Parish—to his find, and this gentleman in connection with Professor Reichenbach duly named and described it. It was not, however, until about ten years after its discovery that its first flowers appeared in England, this event taking place in the famous collection of Sir Trevor Lawrence, at Dorking.

The most convenient mode of growing this species is in baskets, which may be suspended from the roof within a foot or two of the glass, thus enabling the plants to receive abundance of light, which they enjoy. When the sun, however, is powerful the plants must be protected from its rays by means of shading. When the young growths begin to push forth, that is the time to begin increasing the supplies of water, and when they are approaching maturity the supplies may gradually be decreased, at the same time giving the plants as much air and light as is consistent with safety. The summer temperature may range from sixty-five to seventy-five degrees Fahr. during the day, and about sixty degrees at night, while for the winter these figures may be reduced by five or eight degrees.

Isleworth, London, W.

John Weathers.

The Egg-Plant Blight.—The Egg-plant has been seriously diseased during the present year, and the crop is light from the inroads of a blight. Complaints have come from various sources, but nowhere have the losses been greater than in some portions of Gloucester County, New Jersey, where this crop covers large areas, and where market-growers sometimes plant as many as fifteen acres. A microscopic examination of the diseased and drooping, half-developed plant reveals a Fungus in the pale yellow leaves which, after sending its fine threads all through the tissue, soon concentrates in small areas and produces brown spots, over which are developed minute dark specks. These specks bear the multitudes of minute, colorless spores or reproductive bodies that are capable of germination and producing the disease in healthy parts of the same or other plant. The fruit upon the sickly plants is small, and before reaching half the normal size the skin turns brown in patches, followed by a dark pimply development of the surface, which ultimately spreads over the whole fruit. Before this, however, the fruit usually falls to the ground, and shortly becomes a soft, spongy, rotten mass. These decayed fruits, when left in the field, become the origin of infection for other fruits; for each pimple—and there are thousands upon the same “egg”—is a spore-bearing body, as are the black specks above mentioned as occurring upon the brown patches of the leaves. This Egg-plant blight or rot is closely related to the black rot of the Grape, and the same differences between leaf and fruit-form are manifest. The species is *Phyllosticta hortorum*, Speg., and belongs to a large genus of destructive parasitic Fungi. In the laboratory it has been an easy matter to propagate the disease from one fruit to another, the infection showing itself in thirty-six hours. There is but little doubt that by spraying the vines with Bordeaux mixture or carbonate of copper in ammonia the trouble can be checked.

Chrysanthemums.—It is about time to lift Chrysanthemums from the open ground. All plants should be dug around at least four days before removal, and a full week would be better. I use a sharp spade and thrust it in the ground around each plant in a circle, which about equals the circumference of the pot in which it is to be placed. The digging around cuts off the long roots, after which young fibres are formed within the circle, and they commence feeding at once. If the long roots are cut at the time of lifting the food supply is rudely checked, the plant wilts and often the buds are crippled. The disbudding of all plants should be proceeded with as soon as the buds are as large as Radish-seed. Do not shrink from thinning severely. On one growth of stem from the surface of the ground of a plant of *Gloriosum* I have to-day removed forty-seven buds, leaving seven. These will be reduced to five, or perhaps to three, before the time of blooming. The flowers will be not less than five inches in diameter, and will present nearly as much coloring as if the whole crop of buds had been left, but with this difference, that a few finely developed flowers will take the place of many puny ones. By the end of the month it will be necessary to have all Chry-

santhemums where they may be protected in case of a sharp frost, which almost invariably occurs here between the 27th of September and the 8th of October.

The Forest.

The General Condition of the North American Forests.—II.

THE visitor from Europe is particularly surprised at the extraordinarily long and numerous wooden structures which the railway train sets to vibrating in crossing the water-courses. In America the streams retain a freedom of movement of which they make full use; one year here, another there. From high mountains the bed of a stream looks like a broad white band of water and gravel banks, with green, wooded islands between.

Streams are a good indication of the state of cultivation of the surrounding country. Those which from year to year discharge their clear water into the sea, and through the year scarcely vary in their water-level, come from an undisturbed wood-land. Their banks are held fast by the roots of the trees in the region of the head-waters, and in the mountains the water gathers slowly from the woods. Such streams one sees now for the most part in uninhabited regions only; in the Island of Hokaido, in northern Japan, for example, I have found such.

Streams which during the rainy season or during the season of melting snow flow turbid, and during the rest of the time clear, showing in ordinary weather small variations in their water-level, rise in woodlands, and flow through arable land, part of the soil of whose roads and fields the rains wash into the streams. Of this kind are the streams of Germany and France.

Finally, streams which year by year flow with turbid water, or which, at least, through the rainy season rush through the cultivated plains to the sea with swollen floods, here carrying away soil, there heaping up gravel-banks, come from an up-country in which the forest is almost entirely wanting, or the deforesting is under full headway. Such streams one sees, for example, in Ceylon, where the English, with plantations of Tea, of Coffee and of Cinchona, have begun the destruction of the forests and the woodlands of the mountains. Such streams are numerous in Japan, Spain and northern Italy. There the streams are feared whenever it rains a few days longer than usual. The American streams approach this stage. In their unrestrained impetuosity they vie with each other in bringing ruin upon their bottom-lands, which, as a rule, contain the best soil. That a change must have taken place in a river is clear when during the rainy season it undermines its banks covered with trees that have stood for centuries, and finally sweeps them away in its floods. Instances of this are numerous in America, and speak plainly to every one who can and will see, more plainly than all the books upon the influence of the deforesting of the mountains and the plains upon the water-level of streams. The deforesting of the Adirondacks through fire and in useless attempts to take the mountains for agriculture, causes a perceptible change in the water-level of the Hudson, which during the dry season is fed with the moisture of the earth in the Adirondacks. Formerly Peekskill was a water station of the New York Central and Hudson River Railroad. This station had to be abandoned because during the dry season the salt water forces itself as high up the stream as Tivoli, and salt water is unsuitable for feeding locomotives.

Although the American engineer is familiar with the increasing variation in the level of the streams, one sees but few efforts to regulate their flow, which, indeed, would involve a mere waste of money, as long as the average level of high water is yearly becoming higher. Moreover, many look upon the deforesting of the mountains with indifference, because they believe that the forest, with its beneficent influence, can be replaced upon a magnificent plan. Their idea is to fill enormous reservoirs with water during the rainy season, and then to permit the contents to flow throughout the cultivated lands. But for the filling of such reservoirs a considerable surface of soil which may collect the rain is necessary. It is to be hoped that the rain will be so gracious as always to fall with due regard for human safety, for the breaking of the reservoirs might have worse consequences than a cloud-burst. To me it seems much safer that the great amount of money which permanent water-works would require should be utilized in buying up the mountain lands and preserving their forests. This would be good policy even without taking into account the fact that these natural reservoirs bring in money, while the artificial ones only swallow it up.

In spite of the outrageous management of the forest everywhere in the United States, I am inclined to believe that, partly of itself, partly with some little help, it will return to its beneficent condition, if in the future it should be possible to preserve it from fire. Danger of fire in the forests in the civilized part of Europe has become a rare thing; at the least fire every one hastens to put it out, and the Government has power to compel all to help.

In India the number of forest-fires is lessened yearly, thanks to the energetic measures of the Government and the watchfulness of an efficient body of foresters, while young growth springs up on the protected plains.

In Japan, a smaller country, fire and the axe have already nearly completed the work of destruction. The brave nation is laboring with the utmost zeal and with great outlay of money for the restoration of the forest on the shrub-covered mountain slopes, and for the preservation of what still remains.

In North America the practice of burning forests has become customary, even in cases in which it is entirely without reason. How can anything else be expected from the descendants of a nation that has no forest, and therefore knows nothing of the blessings of a forest? Closer study of the causes of the burning of the forests forms an instructive, if not an edifying chapter. We see what man can bring to pass in a country of such highly vaulted elbow-room, in a country where the most complete individual liberty seems to be the chief principle, in a country whose laws for forest-protection are empty threats, because the ignorant and unprincipled cannot be compelled to obey them.

According to the report of Professor Sargent, one million acres of forest were burned in a single year (1879-80), and with it twenty million dollars' worth of property was destroyed. The causes of these fires have been ascertained, as follows: 197 fires resulted from burning over pasture lands; in 1,152 cases fire started in making forest-clearings; 508 started from locomotive sparks; 628 from hunters' fires; 72 from camp-fires; 35 from pipes and cigars; 12 from prairie fires; 9 from charcoal-burning; 32 from lightning; 56 were kindled by Indians; 10 by lumbermen; 2 by tourists; 262 were kindled maliciously; in 2 cases fire is said to have been started by spontaneous combustion; 3 times wood-cutters and 3 times unknown carelessness set the fire. This makes a total of 2,983 cases.

Let us examine further the fires started maliciously and those caused by locomotives, hunters and campers-out, 1,470 in all. The injury that the railway does to the forest-interests is very serious. One who travels to-day in North America must grow accustomed to the charcoal heaps on both sides of the railway, if he would have any pleasure from the beauty of the landscape. From the railway the fire has encroached for countless miles upon the forest. Upon the oldest railways the danger of fire is reduced yearly by constant burning of the trees from the clearing on both sides of the road-bed. Upon such clearings it would be an easy thing to cut off the fire from the forest with a safety-ditch. It appears to me that there is no other expedient than to make a cleared belt along the tracks as soon as possible. At all events, this does more good than the spark-arresters which the law prescribes, since, in spite of all laws, the locomotives run without them.

A characteristic result of the boundless freedom of the individual at the cost of the people is presented in those cases in which hunters and tourists camping or traveling in the forest cause the fires. In the year 1880 they kindled 700. As far as my experience in western America extends, the sportsmen are careful to burn the under-brush, which in the primeval forest contains generations of future forest-trees, in order that they may be less hindered in their aim. In other regions the woods are fired in order that the game throughout particular districts may be driven together. Comment on this is quite unnecessary. Forest-thieves, too, start fires, especially in the Government forests, in order to obliterate the traces of their theft.

With reference to the Yellowstone Park, the possession and the pride of the whole nation, H. Winsor says in his "Guide for Tourists":

"It is to be deeply deplored that because of the carelessness of campers-out, many of them cultivated people, vast stretches of forest have been destroyed by fire. The fires have resulted from neglect of the simplest precautions as to camp-fires. In consequence of this it is not at all unusual to be obliged to ride in the park for miles and miles between black tree-stumps instead of in the refreshing shade of the green forest. This thoughtless destruction of the forest should be checked by severe punishment of the offenders."

It should be provided by law that any one who causes a fire

shall be held for the injury done, and the amount of damages should be equal to the value of the woodland destroyed. But the injury done to the forests by overthrowing confidence in the security of forest-property, by discouraging the investment of money in forest, by the destruction of the young growth, and by the effect upon the fertility of the soil would still remain without mitigation.—From "*The Forests of North America*," by Dr. Heinrich Mayr.

Correspondence.

Wayside Beauty.

To the Editor of GARDEN AND FOREST:

Sir.—The several articles upon "Country Roads" which have appeared in GARDEN AND FOREST we have chosen to receive as words of personal approval, so well has their sentiment chimed with the spirit which has been moving us to better and to beautify a short bit of road which leads us daily to the station on the one hand, and to the village, less than a mile away, on the other.

A very few years ago this road was at times so deep with mud that it would become nearly impassable, and farm wagons especially were compelled to make quite a long detour to reach the station from the turnpike or from the village. The neighborhood becoming more popular and more populous, and the demands for better roads increasing, the county officials were induced to take this particular piece of muddiness in hand. The grade was first improved by cutting, filling and ditching. There was then laid down a good bed of the rock most convenient to the locality and known even to the geologists as "nigger head." This is an extremely hard *gabro*, occurring mostly in nodular masses and very difficult to crush, but when once in place and tightened by the pressure of wheels it makes, by reason of its toughness, perhaps the best of road-metal. The neighbors now came to the front, and of their own means and motion they covered this rough stony bed with a layer of oyster shells of from four to six inches in thickness. These were rapidly ground up on and near the surface, the finer bits trickling through and forming a compact mass below. Last winter's observations showed us that to attain perfection, and to make a model of our hobby, we should have still further to raise the middle of our road-bed a few inches—this time instead of oyster-shells we determined to try crushed blue lime-stone, which we brought by rail from near Waynesborough, Pennsylvania, the railroad giving us special rates. Of this stone, broken to pieces the size of chestnuts, we made a last covering of about four inches in thickness. The road is now perfectly smooth and hard, and is nearly as white as when covered with the shells. This whiteness, to which some might object, is by no means glaring or disagreeable, as the road is mostly shaded. On the contrary, it is found to be very convenient by night in enabling one to keep the track.

In spite of repeated insinuations of untidiness, and, indeed, of outspoken demands for the use of the scythe and the axe, we have succeeded thus far in preserving vegetation quite undisturbed, with the exception of pruning some overhanging and interfering tree-limbs. On the ugly red slopes of a long cut, through which the road passes, and also on the face of a rather steep bluff, we planted a good lot of Chinese Honeysuckle. This has outdone expectation, and has given us the densest walls of green in place of the ugly scored banks which were continually washing down or sliding into the road-side gutter. The fragrance, too, of its flowers fills the air, as well as our senses, with its sweetness, and bees and humming-birds abound. The other trees and shrubs which border our lane are essentially our own—that is, are American—and occur in sufficient variety to give a caste to the seasons. The Spice-wood comes out with its small yellow flowers to insist that spring has really come, and warns us later by its red berries of the summer that's waning. Why is it, by the way, that this Benzoin, with its fine foliage and generally attractive habit, has not become more commonly domesticated? I have been pleased to see it named in GARDEN AND FOREST among other commonly neglected native shrubs as worthy of a place upon our lawns.

The Blackberry-bushes along our road-bank were this year simply charming. Owing to the mild winter their long reeds of last year were not killed back, but becoming covered with flower-shoots and bending gracefully away from the high banks, the effect was most unusually beautiful. Wild Grape-vines are smothering the life out of some decrepit Locust-trees, and are competing hard with Honeysuckle and Poison Ivy for every bit of space and light. Wild Cherry, Viburnum and Dogwood contribute their part in flowers and shade, each in its time, and a number of Sassafras-trees save themselves

for the dying year, when they flare out with their splendid foliage of crimson and orange. Charlock and Hedge Mustard have established themselves over certain areas, and are very brilliant when massed in flower; but the gardeners pass them with an evil eye askance, and sometimes come back with a scythe or hoe. Just now the Compositæ are beginning to have their day. The Bonesets, Sunflowers, Asters and Golden Rods are conspicuous. At one point the road is hedged in by a dense mass of the pretty Jewell-weed in full flower, and all mixed and matted by a rank growth of Bunch-weed, whose little clusters of white-winged flowers mingle becomingly with the yellow, dangling nectaries of the Balsamine. Such are the more noticeable details of vegetation which we have succeeded in letting alone, and which make of this oft-traveled road, for some of us, a never-ending source of pleasure and interest. Should we hope for as much of a well kept, tidy road-side? We are encouraged to believe that others are beginning to take the view of these weeds that we ourselves take, and still others, alas! are so indifferent as not even to wish to destroy. This at least gives us hope of saving our wild bank as Nature makes it for us.

Baltimore County, Md.

B. W. Barton.

Shrubs on Tree Borders.

To the Editor of GARDEN AND FOREST:

Sir.—The short extract from Gilpin's "Practical Hints," in GARDEN AND FOREST of September 3d, page 426, touches a subject of vital importance in the development of landscape effect, which very few people appreciate as it deserves. The opening sentence gives the keynote of what I refer to: "Groups of large trees should be accompanied by shrubs to connect them with the lawn."

Any one who will look across a meadow or lawn at a line of wood the outer edge of which still retains its fringe of wild shrubbery presenting a mass of foliage impervious to sight from the ground upward, and will then contrast it with the more common case, in which all the shrubbery and low-growing limbs have been cleared, and the eye penetrates perhaps the whole breadth of the wood through a maze of bare trunks, will appreciate the superior beauty of the former. And yet, nine times out of ten, the first work of "improvement" on a new place is to set a gang of laborers to work at grubbing out all the wild shrubbery, and they always begin at the outer edge, where every leaf should be sacred.

I have grown tired of hearing the announcement from proprietors who seek my aid in developing the beauty of their grounds that they "have had all the underbrush grubbed out, so you'll have no difficulty in seeing through anywhere."

Many men, who have a genuine love of natural beauty, fail to appreciate this till their attention is called to it, when they acknowledge with surprise that they had never before analyzed the nature of the obviously superior beauty of a mass of foliage as compared with an open wood when seen across a lawn.

Recent Publications.

Report of the Division of Forestry for 1889. By B. E. Fernow.

It may be that there is an author's edition of the Report of the Chief of the Forestry Division for last year, but we have not seen one. It will be found, however, in the general report of the Secretary of Agriculture, and although it is not so long as usual, it contains much important matter, which should be read by every person in the country who has the interests of our forests at heart. If the Forestry Division should ever become an executive department, charged with the management of the forest-lands which belong to the nation, its duties in that direction would be clear. If, on the other hand, it is to be simply a bureau of information there is a question as to what particular kind of information it should acquire and disseminate. With the present appropriation the Department is unable to command the services of competent assistants, and, of course, such systematic work as was outlined in the report two years ago cannot be undertaken. In the absence of adequate facilities the work done by the Department has been in a certain measure desultory, although the investigation concerning the prospects of substituting metal ties for wooden ones on railroads is considered by Mr. Fernow to be highly satisfactory. The biological studies in regard to timber trees have been carried on, although slow progress has been made for lack of means. Mr. Roth, of Ann Arbor, has furnished a comparative study of the woods of three prominent southern Pines, and these will be printed, together with the monographs

on the life-history of those trees. The monographs now on hand, and still unpublished, comprise the following species: The White Pine, by Professor S. V. Spalding; the Norway and Pitch Pines, by Professor William Flint; the Hemlock, by Professor A. N. Prentiss; the two Spruces (*Picea nigra* and *P. alba*), by Miss Kate Furbish; the Long-leaf, Short-leaf, Loblolly and Cuban Pines, by Dr. Charles Mohr. It is to be hoped that the publication of these studies will not be delayed, as they probably constitute the most valuable work which has been accomplished by the Division during the last three years. They are to be illustrated by wood-cuts of the highest order. Among the other work attempted during this year is a canvass among the railroad managers relating to supplies and prices of wooden ties; a canvass as to the needs of the cooperage industry, which uses two hundred and fifty million cubic feet of wood per annum, and the beginning of an investigation of the supply of timber needed for carriage-building; but the completion of the last inquiry has been deferred on account of lack of funds. Considerable labor was given to preparing an exhibit for the Paris Exposition and making forestry collections for the National Museum.

Mr. Fernow again points out the perplexities he experiences in distributing according to law "valuable economic tree-seeds and plants." Of course, tree-seeds, as a rule, do not permit of long storage, and must be carefully handled and rapidly disposed of, or they will lose their power of germination. Few people know how to handle the seeds except the kinds most easily grown, while the length of time before a plantlet will grow to a size fit for transplanting wearies the settler's patience. As might be expected, the reports from the seeds and seedling distribution of former years have been most discouraging.

A compilation which attempts to show the status of the forest-timber culture entries from the reports of the Land Office proves that the results are far from satisfactory. It may be that greater success will be gained from the entries of latter years, because of increased experience and because the timber-claim planting is now often done by contract by persons who make a business of it. Yet the consensus of unbiased testimony goes to show that this planting, as a rule, does not produce the results desired and has chiefly been used as a means of speculation in Government lands, either with this design from the outset or as a necessity after a failure to obtain land by timber-planting. Of course, there is some planting of wind-breaks and groves done on homesteads which have succeeded better, but the amount of tree-planting is infinitesimal, when compared with what is necessary to ameliorate the climate, and it may as well be admitted that the reforestation of the plains must be a matter of co-operative enterprise if it is not a national work.

Under the head of "Proposed Work," Mr. Fernow gives a condensed statement of what he thinks the character of the information should be and how it should be obtained if the Department is to continue simply as a bureau of information. In the first place, the Government needs information as a basis for action relating to its own timber-lands, and to enable it and the general public to appreciate the true relation of the forest-interests of the nation to its economical life. Again, consumers of forest-products need information which will help them to use the same economically and advantageously, and finally, the owners of natural woodlands need to know the best method of managing them for reproduction, and forest-planters need to know how to start and cultivate a timber crop. Government action can have no rational basis except carefully obtained and digested statistics, and statistics of forestry matters are among the most difficult to collect, and yet their collection is all the more desirable because of the difficulty of estimating and comparing present supplies and future requirements. But with the present organization of the division no comprehensive collection of accurate figures can be contemplated, however desirable and urgent such a work may be. Outside of these statistical inquiries there is a wide field for the study of our timber trees in the biological and technical direction. We are by no means certain as to the qualities of our timber trees and their adaptability to forest-uses, and still less do we know upon what conditions of soil and climate these qualities depend. Not only is the engineer and architect interested on this point, but the planter is as well; for he may be led to use a species which, while it may grow well in his locality, does not in the end develop those qualities for which it is most highly prized. We know very little, too, about the life history of timber trees, and this knowledge is the only basis of successful forestry. We have learned much about various trees in the nursery and their requirements for ornamental planting, but the behavior of these trees in the forest

differs greatly from their habit in the open ground, and as forestry means tree-culture for profit, it is essential that the relative growth of forest-species at different ages throughout their entire life shall be known, and at what age the most desirable quality and profitable size is reached. As an instance of the practical value of such knowledge Mr. Fernow calls attention to many plantations of Black Walnuts in the western states, which grew rapidly for ten or fifteen years, and have become since then a disappointment by their slow growth.

In order to settle many vexed questions in forest-culture and to obtain positive evidence as to the best method of planting, and the best timbers to use in arid regions, it is desirable to begin systematic experimental plantations. The co-operation of experiment stations now existing in treeless regions, as well as of private individuals who have special facilities, is therefore invited to establish such experiment plantations upon a uniform and centrally directed plan, and it is further suggested that the authorities in charge of the military reservations of the west be requested to aid in carrying out this plan.

To the report proper is added an interesting appendix on "The Influence of Forests on Water Supplies." We have no space for quotation here, but what has been discovered by careful investigation in other countries is very tersely set forth, and it hardly needs to be added that these figures do not confirm Major Powell's theories as to the destructive effects of mountain forests upon the flow of streams which take their rise among them.

Notes.

We have received the first number of the *Western Garden*, a new monthly journal of horticulture published at Des Moines, Iowa.

A meeting of the New Jersey Horticultural Society will be held at the College building in New Brunswick on Monday, September 22d, beginning at ten o'clock. This is the fifteenth anniversary of the organization of this Society, and it is especially requested that all those who were present at the beginning, as well as those who have since been identified with the Society, should make an effort to be present on that occasion. The exercises will be interesting and an attractive exhibition is promised.

Although the double site selected for the Chicago Fair was contrary to the advice given by Mr. Frederick Law Olmsted, it is to be hoped that he will accept the position of Landscape Architect which was offered to him. So far as spectacular effect is concerned, it was folly, of course, to divide the ground, but a satisfactory plan can no doubt be arranged. As usual in such cases, the trouble from interference and opposition in carrying out the artist's ideas will probably be more serious than the difficulties in the natural conditions of the double site.

The most interesting plant at the last monthly exhibition of the Massachusetts Horticultural Society was a hybrid *Cypripedium* shown by Messrs. Pitcher & Manda, of Short Hills, New Jersey, and named *Arnoldianum*. The plant was particularly interesting since it has been raised within two years, which is probably the quickest time on record for the flowering of a hybrid Orchid from seed. This rapid development is more surprising since *C. concolor*, one of its parents, is a very slow grower. The other parent is *C. Veitchii*, and the hybrid shows the form and color of both parents in its flower.

Germany now counts nine schools of forestry, some of which at least are connected with her greatest universities; and that the professors who instruct in this branch are as highly honored as any is shown by the fact that the rectorship of the University of Munich is now held by Dr. Hess, Professor of Forestry, while last year his fellow at Giessen, Dr. Gayer, held the same position there. Only two forestry-schools exist as yet in Great Britain, one connected with the University of Edinburgh, and the other with the Indian Engineering College at Coopers' Hill under the control of the Government of India.

The phylloxera has invaded the Department of the Marne, whence comes all the French champagne. The Prefect of the Department has sent a report on the subject to the Minister of Commerce, which leaves no room for doubting the evil news. He says that the Vines over a stretch of country extending from Vincelles to Treloup have a pale yellow tinge instead of their natural green, and that the small fibrous roots are covered with nodosities. The Minister has sent Monsieur Douette, a professor of agricultural science, who studied the phylloxera in the south of France, to Epernay. He is instructed not to hesitate, if he judges well, to apply the Government rules for stamping out the disease. The Prefect says the

whole country is terrified at the visitation. It is also reported that the phylloxera has appeared on the Rhine, and the vineyards at Mayence, Rudesheim, Bingen and other places are attacked and great alarm prevails among Vine-growers.

Mr. William Tricker writes that the flowers of *Nymphaea Mexicana*, which are now open in Staten Island, are much larger than those he took to the Boston Exhibition, and the plants are blooming more freely than those of Marliac's supposed hybrid, known as *Chromatella*. It will be remembered that Mr. C. G. Pringle, in our issue of August 27th, expressed a suspicion that this *N. Mexicana* is identical with *N. flava*. We hope that some one who has the good fortune to possess all three of these Water Lilies will take the pains to compare them and note their points of resemblance and difference under cultivation.

As an illustration of the influence of different soils and situations upon different kinds of Narcissus, the Rev. W. Wilks, Secretary of the Royal Horticultural Society, in a note on the Daffodil Conference, published in the Journal of the Society, says: One well known grower writes that Horsfield's variety never has given him one decent flower, although he has tried to grow it for a dozen years, while with Grandis and Empress he invariably succeeds. Another experienced grower writes that with him nothing equals Horsfieldii. The first grower lives on light, dryish, sandy loam, in the south of England, while the latter lives in the north, where rain is never a stranger and the soil is generally heavier.

A recent issue of the *Gardeners' Chronicle* contains an interesting account of the Alpine garden of Monsieur Boissier, which lies in a sunny nook in the Jura at an elevation of some 2,000 feet. The plants from high glacial regions flourish in the hot suns here because of the perpetual humidity which saturates the atmosphere from the evaporation of the abundant water which rushes down on every side. But damp as the air is, every provision is made to prevent the evaporation of moisture from the soil about the plants, and one of the means employed is worth notice. All the more tender species are surrounded by small stones, usually calcareous, and which, broken up into little pieces, cover the soil all round the plant. A splendid white flowered *Soldanella minima* was growing, covered with bloom, in a rock, which yet seemed excessively dry; this is a proof that these white stones scattered over the ground preserve the coolness and moisture of the soil, not only round the roots, but also round the aerial portion of the plant, the flowers and the leaves.

Mr. H. W. Wiley, the Chemist of the Department of Agriculture, has just published a bulletin concerning the cultivation of the Sugar Beet in the United States. The purpose of the bulletin seems to be to indicate the general principles which should be followed by those who intend to embark in this industry, and especially to prevent beginners from starting wrong and wasting time in an attempt to solve problems which have already been faced and overcome. From what is stated of the history of the industry in this country it appears that there have been many failures and few successes, and it is to be feared that the reports of remarkable profits in special instances may encourage many to enter into the business without adequate forethought and preparation. The methods of manufacturing sugar from the Beet have been so far perfected that there is no longer any need of public experiment in this branch of the business. The problem here is the agricultural one—that is, the selection of suitable soil under proper climatic conditions, and proper methods of planting, cultivating and harvesting the crop. In a general way, the coast valleys of California, and probably some large areas near the coast in Oregon and Washington, certain parts of the Dakotas and Nebraska, a few localities in Minnesota, Iowa, Michigan and northern Illinois, Indiana, Ohio and New York, seem to present favorable conditions for growing the Sugar Beet; but it is only in restricted areas where the conditions are exceptionally good even within these specified limits that we can hope for success. Many attempts have been made during the past twenty-five years to introduce this industry into the United States, and factories have been located in New England, Delaware, Illinois and California; but, with two exceptions, all these ventures have met with financial disaster. A factory at Alvarado, California, has been successfully operated for a number of years, and another one at Watsonville, in the same state, has been successfully operated for two years. From these successes it is reasonable to infer that others may succeed when all the proper conditions are supplied; but every attempt to erect a factory hurriedly or in a location where the capabilities of soil and climate are untried should be discouraged.

The Language of Science.

NOT long ago we published a complaint that young persons were repelled from the study of botany because of the hard Latin and Greek names which were given to the plants. We have never discovered any basis for this charge, and find no reason to believe that the science would have more devotees under any system of nomenclature which could be devised. It is not meant by this that scientific names of plants could not be improved or that better rules for naming them could not be framed, but there is no evidence that the imperfections of the system are so serious as to deter any one from studying plants or to hinder to any appreciable extent those who have begun the study. A new charge, but one somewhat similar in its character, has recently been made, which perhaps deserves a word of consideration. In his address before the Florists' Convention (see p. 421), Mr. E. S. Carman, while recognizing the necessity of a plant nomenclature of general application, and therefore accepting Greek and Latin names as the best, stated nevertheless that the words which botanists use to express processes, conditions, etc., in the life of plants are so absurd, irrational and preposterous that the study of botany is rendered repulsive to these young people. Mr. Carman's paper was on hybridizing, and to prove his case he cited such words as "dioecious," "monœcious," "gyno-dioecious," "proterandrous," and so on, stigmatizing them as bombastic and abominable.

In the first place, it may be said that young people, or old people for the matter of that, who study botany as they should, and investigate plants themselves instead of learning lessons from books, have occasion to use scientific language only when they have some scientific ideas to express. Just as soon as one has a new idea there comes the necessity for a new word. Mr. Carman himself uses such big words as "organography," "morphology," etc., because he wishes to express a well defined science, and these terms have been selected for that use. He cannot express his meaning so distinctly and concisely in any

other way, and yet these words are as strange to the illiterate and to the young person as are any of those he uses to prove his case against the botanists. The fact is that the same charge can be brought against any other study. At the very outset of his arithmetical studies the child must become familiar with such hard words as "multiplicand" and "dividend" and "minuend," and in geography he is immediately confronted by "hemisphere" and "meridian," "equator," and many more which are quite as trying to him as any botanical term. There is no need of bringing illustrations from other sciences. Open any systematic treatise on birds or insects, on geology or medicine, and just as many "hard words" will be found as the botanists use. The reason for this is that scientific language is necessary in a scientific treatise.

But what do the critics mean by "hard words"? Not long words surely. If this question was pressed a little, perhaps the answer would be "words that are not in common use." But the subjects discussed are not subjects of ordinary conversation, and, therefore, there can be no common word to represent the ideas and processes in question. Perhaps Mr. Carman, who considers "dioecious" a hard word, would say that "deciduous" was an easy one. This is simply because the latter is more frequently used, but to the "young person" who learns them one is quite as easy as the other. But however this may be, the fact remains that it is utterly impossible to write a scientific treatise unless there are specific terms to represent the objects, the attributes and the processes which must come constantly under discussion. The only question is how should the words that are needed be formed. Now, the same reasons which make it advisable to use Latin and Greek for the names of plants, and in fact for technical names in all sciences, would seem to imply that the roots of these universal classics should be used in forming all the new words in scientific language.

This language is not constructed primarily to make science attractive to the young, but to furnish a means of complete and precise expression for those who are prosecuting particular studies. Any one with a slight acquaintance with Latin and Greek can easily form a word which will accurately express a new idea, and the reader will comprehend its meaning even if he has never seen it before. And many people who have never studied Latin and Greek, but who have become familiar with the roots of certain words which are often used in any given science, can not only understand new terms, but can construct them in correct form. Hugh Miller was not acquainted with any classical language, but he used the Latin and Greek terminology with all the facility of a skilled linguist.

Of course, all this is elementary doctrine, and there ought to be no necessity for such an argument even in a popular journal. But we believe that botany should be studied much more generally by young people than it is, and, while we have no fears that they will be deterred from it because scientific language is employed, we do have fears that some of them or their parents may be discouraged by careless criticisms, which magnify supposed difficulties, or by artful ridicule of the methods of the most advanced students of the science.

It may be that some of the criticisms upon the management of the Yosemite Reservation have been unduly harsh; but since the matter has become a subject of general discussion, and the plain truth is slowly appearing from out the mass of conflicting statements, it is growing more and more evident that the crowning charm of wild beauty which invests this valley is vanishing as swiftly as possible before the blighting touch of man. The details of the defacement are too sickening to recapitulate; but mutilated trees, meadows scarred with the plow, and acres of blackened stumps well justify the statement of John Muir, who has known this valley for more than twenty years, when he says in the *Century Magazine* that everything accessible and destructible is going more rapidly to

ruin here than in any other valley of the Sierras, although this is the only one under the special protection of the Government; and he adds that by far the greater part of this destruction of the charm of wildness is of a kind that can claim no right relationship with that which necessarily follows use. But the larger features of the park, especially its waterfalls and streams, are in danger from attacks upon the region without its borders. The time is at hand when lumbermen will begin to clear away the woods and herders will drive in sheep and cattle to browse and trample the life out of the ground, and the result will be that not only the valley will lose the frame-work of the surrounding beauty, but the streams which flow into it will become turbid and irregular torrents.

With these facts in view one can hardly understand why Congress should any longer delay action upon the bill offered by General Vandever, which extends the limits of the reservation so as to include the watershed of the important Yosemite streams and many beautiful groves and cañons, mountain lakes and meadows. The Act in its provisions is similar to the Tulare Forest Bill which has so recently been enacted. The enlarged reservation is to be under the control of the Secretary of the Interior, who is to make regulations for its management. Of course, the administration of the original reservation will continue in the hands of the state of California. It is not to be assumed, however, that the good people of that state will suffer its name for public spirit, and for an enlightened appreciation of the value of this sublime scenery, to be clouded much longer by the brutality of the men who are willing to barter away its unique beauty for the price of a hay crop. A rational management of the extension of the reservation must exert a wholesome influence on the management of the valley itself, and, therefore, the sooner the new reservation is established and put under national control, the better. This will not only preserve the rare beauty of the region about the Yosemite proper, but it will help to rescue the wonderful valley itself from deliberate ravage, which the civilized world would look upon as a calamity.

MR. WILLIAM LITTLE, who is a remarkably well informed lumberman, has published an open letter, addressed to the Montreal Board of Trade, on the wasteful mismanagement of timber lands in Canada and in this country. He says:

"Contrast the character of the timber manufactured at the present time, running largely into the different grades of culls, with the magnificent black walnut, black cherry, butternut, chestnut, hickory, buttonwood, whitewood, black and white ash, red and white oak, red and white pine which, when not used for fencing or fuel, were burnt up in the log-heaps of Ontario in Canada, and in New York, Pennsylvania, Ohio, Indiana, Michigan and Wisconsin in the United States, only a few years ago, and which, when manufactured, ran largely into the grades of selects and clear lumber. While hardly a thought is given to the matter by the people, we are almost face to face with a problem that must be quickly solved or disaster will surely and speedily follow.

"New lines of railway are being built or extended into districts dependent almost entirely on the timber trade for business; the carrying capacity of the lake marine is being increased at an enormous rate; cities, towns and villages, depending largely on the lumber industry, are enlarging their borders as if the supply was inexhaustible. But timber cannot be grown like a crop of corn; its growth is a matter not of years, but of ages, and when it is once gone it cannot be restored during the lifetime of those now living, while the really good timber of the north Atlantic and lake regions is not only not inexhaustible, as many suppose, but is actually almost exhausted.

"The forests of the vast territory extending from the confines of New Brunswick to the head-waters of the Mississippi are almost on the verge of immediate exhaustion, and yet, so ignorant or indifferent are the people of the United States to the seriousness of the situation, that they are even now higgling about what special restrictions they can impose upon Canadian lumber. Let them increase the duty by all means, if they like—the higher the better, in my opinion—for they will then the sooner know how grievously they have erred and

how imprudent they have been when they are compelled to pay these duties themselves, and Canadians are able to get what prices they want for their lumber.

"But if we continue to stock American saw-mills with logs, taken from our already too scanty supply, to forestall the markets in advance of our own manufacture, and keep slashing away at our timber as we have always been doing, overstocking the markets as if it were something to be exterminated at any cost, and with the Government, the capital, and, I may say, the public opinion of the country, when not indifferent, all arrayed against the forests and animated with the same destructive impulse, we will no doubt soon be able to get rid of the timber, and to get rid at the same time of the most valuable property we ever had, or may ever expect to have, in our country."

The American Elm.

WE published in the issue of June 11th a portrait of what may be considered a typical specimen of an American Elm (*Ulmus Americana*), planted by man, and allowed to develop during a hundred years all the grace and beauty peculiar to this tree. The American Elm, however, differs in its habit of growth considerably and assumes various forms as conditions are more or less favorable to its growth. A more recent number of this journal (Sept. 10th) gave an illustration of another form of this tree with pendulous branches which sweep the ground. A not unusual type of the American Elm is the one represented in our illustration on page 467. The trunk and principal branches of this tree are clothed along their whole length with short, lateral, feathery branchlets, giving to the tree the peculiar appearance which is well reproduced in our illustration. There seems to be no particular reason why some individuals should develop these lateral branches and why some should not. Many Elm-trees do it, however, and it is not an unusual sight to see two trees growing side by side under precisely similar conditions, the one with a naked stem and main branches, and the other clothed as fully as the tree of our illustration, which is, moreover, a remarkably fine specimen. It is growing on rich intervalle land in the town of North Sandwich, in New Hampshire.

We are indebted to Dr. William Herbert Rollins, of Boston, for the photograph from which the illustration has been made.

Effect of Forest-Mismanagement on Orchards.

I DO not intend here to rehearse the influence which the forest exerts upon fruit-culture by reason of its protection against cold and hot winds. The value of a properly disposed shelter-belt for the orchard is well understood. It is also well known that by opening up the country to the sweep of the northern winds the cultivation of the Olive in northern France was made impossible, and other such results of injudicious deforestation, of local as well as general character, are on record. I wish to show that not deforestation, but the mere mismanagement of the forest in the way of leaving large parts of felled trees in the woods and in allowing fires to run through the woods, works injury not only to the forest itself, but to the neighboring orchard. It is a well known fact that a large proportion of the beetle larvæ which infest living trees cannot exist in a thoroughly healthy and vigorously growing tree; those larvæ in particular which are found in the cambium layer between the wood and the bark would be drowned in the sap of healthy trees. They are, therefore, mostly found in those trees which, for some reason or other, are less vigorous or on the road to decay. When a fire has run through the Pine forest, or when a leaf-destroying caterpillar has ravaged the foliage and thus reduced the vigor of the trees, these beetles find a most favorable breeding place in the weakened trees, and their larvæ multiply rapidly and finish the work of destruction in short time. For this reason it is often necessary to cut millions of feet of lumber and cordwood at once, or it will be entirely ruined. While, then, these little insects—belonging to the families *Bostrichidae* and *Scolytidae*—are great enemies to the forest itself, there is no doubt that many of the insects injurious to our fruit and shade-trees find their most favorable breeding place in the trunks and limbs of the scorched or freshly felled trees. The frequent forest-fires and the failure of the farmer and lumberman in disposing of large parts of the felled trees must be considered as among

the principal causes of the prevalence in North America of these insect borers. The horticulturist may destroy the borers in his orchard or vineyard, but the mismanaged and maltreated forest makes a fertile breeding ground for them and replaces those destroyed by the watchful orchardist.

To substantiate the assertion, the following examples may be cited:

One of the most dangerous enemies of the orchard, the Flat-headed borer (*Chrysobothris femorata*) is found to breed in enormous numbers within the trunks of various forest-trees that have been injured by fire.

The Oak-pruner (*Elaphidium parallelum*), which does considerable injury to Apple-trees, is found under the bark and in the wood of Oak, Hickory, Elm and other forest-trees that have been recently felled and left in the woods or that have been reduced in vigor by fires.

Several other species of the same family, among which are *Prionus laticollis*, the broad-necked Grape-root borer, and others often injurious to the roots of the Grape-vine, breed in the trunks and stumps of forest-trees, especially Oak. *Pelidnota punctata*, a large Scarabæid beetle, which destroys the foliage of the Grape-vine, comes from the same breeding place.

One of the dangerous enemies to cultivated Blackberry-bushes, *Agilus ruficollis*, the red-necked Blackberry borer, preferably breeds and multiplies in the wild Blackberry and Raspberry bushes that have been scorched by fires. *Amphicerus bicaudatus*, the Apple twig borer, very injurious to Apple and other orchard-trees by boring in the twigs, breeds in the roots of the Smilax vines which have been killed by fire.

The various species of bark-borers of the Scolytus family, which attack orchard and shade-trees, could be readily kept in check, but for the fact that they breed unmolested and multiply in fallen forest-trees. Such are the Pear-borer, *Xyleborus Pyri*; the Pear-blight Scolytus, *Phloeotribus liminaris*, and the Apple Tomicus, *Monarthrum Mali*. This list of injurious insects, which find most favorable conditions for development in the mismanaged forest and threaten the orchard, vineyard, park and plantation, could, no doubt, be largely extended.

It would be difficult to tell what in amount the loss from these borers may be. We have learned that insect ravages entail the loss of millions. Thus the loss from the Cotton-worm was estimated in one year at almost \$30,000,000. And when we consider that the tree-borer does not destroy the year's crop only, but the crop-bearing tree itself, the accumulation of many years' growth and all the labor spent on it, we may readily see that, in proportion to the extent of orchards and vineyards, the loss must be considerable.

We have, then, here another illustration that all things in nature have their relation, and that if we interfere with their adjustment we are sure to throw them out of balance and suffer accordingly. We have another lesson, which teaches that cultural and forest-conditions are closely related to each other, and that, as we disregard proper forest-management in utilizing nature's gifts, we must bear the consequences in other directions.

Washington, D. C.

B. E. Fernow.

September in the Pines.

SOME flowering shrubs like Cassandra blossom with the first warmth of spring, while others in the same family hold their flowers back from one to four or five months later. Not only is this true of the shrubs, but herbaceous plants succeed each other in the most wonderful and varied beauty from early spring until late autumn. But by the middle of September flowers are scarce on shrubs and trees. Now and then we find a belated spike of Clethra or a fragrant cluster of White Azalea, but none the less attractive is a ramble among the Pines than it was when they were flushed with the glowing colors of the Laurel and Azalea or lighted up with the pure masses of White-Fringe and Dogwood, and fragrant with Magnolia and Wild Rose.

There is no dearth of flowers now, however, only their character is changed. Fragrance and delicacy seem to have given place to bold masses of azure and gold which blend with the gorgeous coloring of the ripening leaves of shrubs and trees. In damp places the Grasses and Sedges are starred with the lovely *Sabbatia* and purple *Gerardias*—the larger *G. purpurea*, the slender *G. tenuifolia* and the broader leaved *G. auriculata* are all here. The Meadow Beauty (*Rhexia Virginica*) is still a beauty, with blossoms and urn-shaped seed-pods. This species is common in all damp places, but *R. Mariana* is scarce here. For years I had vainly searched for this plant, and then to suddenly come upon it in a place which I had gone over many times was a surprise. The leaves are more narrow than are

those of *R. Virginica*, and the flowers are paler and somewhat smaller.

The closed *Gentian* adds its blue clusters of bud-like flowers to our collection, and a few long sprays of Swamp Loosestrife (*Nesaea verticillata*) are admitted as well as some bunches of purple *Eupatorium*. The little Orchid—Ladies' Tresses—must not be ignored, as some of them are delightfully fragrant, and prized all the more as its more showy companions lack this quality. The orange colored *Polygala* (*P. lutea*) is still abundant, and the purple heads of *P. sanguinea* are mingled with them.

Pond Lilies are growing luxuriantly in ditches which have been cut through Cranberry bogs. It is astonishing how quickly these Lilies find and appropriate such places, together with *Brasenia*, *Limnanthemum* and other water plants. Some parts of these ditches could not be more beautiful if they had been stocked and tended with the greatest care.

Great clumps of the Cinnamon Fern grow along the banks, and also the Regal Fern, together with *Woodwardia* and *Dicksonia*, and the Club-moss is creeping at their feet. The Ferns, too, find a place in our collection. By this time they are fully matured and do not wilt as they did in early summer. Now dipping our mammoth bouquet in water we place it in the shade and drive home for the next pleasure, which is the decorative arrangement of this wealth of material.

On the west side of one of my rooms are two windows that reach the floor with only three feet space between them. In this space is a small table. The windows are draped in white. On the floor in front of each window I set a large vase, in which are placed the tall Ferns, with a few long sprays of Golden-rod. The Ferns on either side reach the table, and are glorious in the full light and graceful amid the folds of the white drapery. On the table I mass smaller and more delicate Ferns with sprays of *Sabbatia*. This is the centre of an arch, and no description can do it full justice. The remainder of the collection find places in other parts of the house. Some of the brightest colors look well before neutral tints of heavy drapery.

But our crowning work can be made with the Water Lilies and the other water plants. With a large, old-fashioned tea tray and a good sized, shallow glass dish, with an abundance of Moss to conceal the tray and edge of the dish, one can make a pretty piece of decorative work or a bit of landscape gardening if you please. Beautiful little Sedges and small tufts of some of the wild Grasses are useful here, and tiny Ferns around the edge of the water are charming. All who have the time and inclination for this kind of work will find no end of diversion in such studies of artistic arrangement. And when completed, with a little care the miniature garden will last several weeks.

Vineland, N. J.

Mary Treat.

Botanical Work at the Stations.

THERE are now twenty-nine botanists employed at the various experiment stations, and several horticulturists are doing some botanical work. In the preparation of a bulletin, which is to set forth the character of their senders, a list of ten questions has been submitted to all of them, and the first of these questions is, "What botanical problems appear to you to be of most immediate importance in your state?" It is not to be expected that the problems calling for solution in Maine and Minnesota would be the same as those in California or Florida. However, in making a summary of the replies, one is surprised to find that far the most prominent subject named is "fungous diseases of cultivated plants." There are sixteen who announce this as among the most pressing lines for investigation. In addition to this, several name the particular trouble to be looked into; as, for example, the Peach yellows, bitter rot of Apples, Cotton blight (two), Sweet Potato rots. It is interesting to note that there has been a quite natural division of the fungous subjects among the botanists. Thus, for example, those of the prairie region are confining their attention mainly to the smuts and rusts of the coarser field grains, especially Wheat and Corn. In the south the leading subject for the fungologist is the Cotton crop, while in the central states the vineyard, and in the eastern states the garden crops and those of the greenhouse are more particular subjects of study.

The study of Grasses and forage plants is considered next in importance; some, especially in the far west, are testing the wild sorts under cultivation. The states engaged in this important work are as widely separated as Vermont, North Carolina, New York, New Jersey, Nevada, Nebraska, Minnesota, Michigan, Maine, Kentucky, Iowa and Colorado. In some

states it is the Grasses particularly that are under investigation, while in others the Clovers, Lucerne and other leguminous crops are being considered.

Next in order of importance comes the subject of weeds. How best to check their spreading can only be determined by a thorough knowledge of their habits; and their eradication calls for a concerted action that can be brought about by widespread information and an urgent appeal.

Following the weeds is the consideration of the long neglected subject of our forests and forest-trees, and next comes the question of plants for barren lands. This title is somewhat obscure, as it may mean forests or Grasses or some other plants of less intrinsic value to be used to prepare the way for something better.

But few of the botanists are engaging in the fertilization of plants, including hybridization and all that is understood by breeding. Three indicate this as one of the pressing subjects for inquiry. It is here again that the line of the station horticulturist approaches close to that of the botanist, and very likely a large part of the station cross-fertilization work will be carried out by the former.

Two have selected the relations of climate to vegetation, and two more testing seeds somewhat after the methods of the German seed-control stations. It has already been found that our seeds are not as foul or our seedsmen as vicious as had been alleged. In the far west two station botanists contemplate a study of the influence of irrigation upon vegetation. And still farther west and north, where state-making is not a thing of the distant past, the making of a state flora is considered one of the first things for the station botanist to do.

To come down to a small ending of the list, in more ways than one the returns show that at least one botanist considers bacteria among the more important subjects for study.

It is seen that the topics are broad and various, and for their satisfactory study there needs to be a wide diversity of talent.

Rutgers College.

Byron D. Halsted.

New or Little Known Plants.

A New Cornus.

A VERY puzzling Dogwood has been known for some time to be growing in the region of the Great Lakes. Occasional specimens received were referred to *C. stolonifera*, but not without contradicting some of its most essential characters. In an early day it had been collected by Bourgeau in the valley of Lake Winnipeg and along the Saskatchewan, and much later by Dawson, in the same region. It is also to be found among Garber's collections from Presque Isle. Macoun collected it at Point Pelee and Lake Nipigon, as well as in the Cypress Hills of the Northwest Territory.

In 1886, however, during a botanical survey of northern Minnesota, abundant material in fine condition was secured by Professor L. H. Bailey, and distributed by him as *C. stolonifera*, to which species Dr. Gray had referred it. Professor Bailey was well acquainted with this perplexing form about his early home in southern Michigan, and was never satisfied that it could be really *C. stolonifera*. The Minnesota material was collected along the north shore of Lake Superior, at Vermilion Lake, and at Hunter's Island, upon the British border. In a critical study of all the North American species of *Cornus* it became apparent that this perplexing form represented a distinct species, which was very naturally dedicated to Professor Bailey.* Its range, as at present understood, is about the Great Lakes, especially Lakes Michigan and Superior, and extending northward and north-westward into Canada. Its occurrence in the mountains of Wyoming, near Fort Bridger, suggests a possible southern extension in the mountain region.† The species can be distinguished from *C. stolonifera* by its erect habit, being not at all stoloniferous so far

* *CORNUS BAILEYI*, Coulter & Evans. Erect shrub, not stoloniferous, reaching a height of six or eight feet, with reddish brown, mostly smooth, branches; branchlets and inflorescence pubescent to woolly; leaves from lanceolate to ovate, acute or short acuminate, appressed-pubescent to glabrate above, white beneath and with woolly hairs variously intermingled with appressed ones; flowers in small, rather compact, cymes; fruit white; stone decidedly compressed, flat-topped, with a very prominently furrowed edge, much broader than high.—*Revis. of Corn. Bot. Gazette*, xv., 37 and 87.

† The Fort Bridger specimens were collected by the Hayden Survey, and named *C. pubescens* by Professor Porter, a decision which really came nearer the truth than *C. stolonifera*.

as known, by its much duller and browner bark, its pearly white fruit, with a large, flattened, square-shouldered stone, and by the white woolliness of the lower leaf-surfaces. It grows over the sand dunes about the lakes, "often in the loosest, shifting white sands," as Professor Bailey writes, and flowers continuously all summer, from June to September. As a handsome, long-blooming shrub, adapted to the sandiest soil, *Cornus Baileyi* well deserves cultivation.

Crawfordsville, Ind.

Foreign Correspondence.

London Letter.

THE fortnightly meetings of the Royal Horticultural Society have this year been exceptionally interesting and useful. Every meeting produces collections of plants of special value in some department of gardening, or some new introduction of more than ordinary promise. There can be no question of the important part such meetings play, or at any rate should play, in the diffusion of horticultural knowledge, for even connoisseurs find them instructive and interesting. In a previous letter I mentioned an exhibition of cut specimens of all kinds of spring-flowering, hardy trees and shrubs, supplied from the Royal Gardens, Kew, and several nurserymen who are strong in this department. Amongst these is the Messrs. Veitch, whose collection in the Combe Wood Nurseries is rich in rare and beautiful hardy trees and shrubs. Few meetings are held at which there are not specimens exhibited from this nursery. At the last meeting the exhibit consisted of a large collection of handsome-leaved hardy trees and shrubs, with a few autumn-flowering things amongst them. I noted the most striking of the plants, which are as follows:

QUERCUS DENTATA.—A Japanese Oak of extraordinary character. The leaves are fifteen inches long by nine inches in width, sessile, with large irregular lobes and almost leathery in texture. In autumn they assume a rich amber and red color. The young leaves are clothed with a soft down, which falls off as they mature, leaving them smooth and green. At present this plant is rare, but the size and beauty of its foliage, and the fact that it is quite hardy and grows freely even in the cold parts of Scotland, ought to make it a favorite.

SALIX ROSMARINIFOLIA.—This is an ornamental Willow with linear leaves five inches long, deep green on the upper surface, silvery beneath, the general appearance being that of a Rosemary, as indicated by the name. It is included by Hooker among the forms of *S. repens*, a British species, but he describes it as having leaves from two to three inches long. It is supposed to have been found by Sherard in the last century in bogs in Scotland. It is worth a place in every garden for the sake of its pretty foliage.

HYMENANTHERA CRASSIFOLIA.—A New Zealand shrub which has proved hardy in the south of England. It grows to a height of about four feet and forms a dense bush, covered with linear gray-green leaves, and in autumn with clusters of pearly white berries.

ARISTOTELIA MACULI.—In the south of England this free growing shrub becomes ornamented with a heavy crop of deep crimson berries, which change to black-purple when ripe. It is usually grown for the sake of its evergreen, handsome foliage. In sheltered places it forms a shrub about eight feet high. Messrs. Veitch exhibited branches of a variegated form, in which the leaves are partly bright, creamy yellow. If as hardy as the green form this should prove a valuable shrub.

LIGUSTRUM SIMONI, a distinct looking Privet in the way of *L. Japonicum*. The leaves are coriaceous, elliptical, deeply channeled and about five inches long. The inflorescence is a terminal panicle of small white flowers. It is said to be the same as *L. compactum*, a Himalayan species introduced in 1875.

CORNUS SPATHII is the garden name for a variety of the Siberian Dogwood (*C. Sibirica*). It is one of the handsomest variegated leaved shrubs we have seen, and if it proves as hardy as the type it will be a most valuable acquisition. As exhibited, it had leaves five inches long by three inches in width, and at least two-thirds of each leaf was colored a rich cream-yellow. It obtained a certificate in July of last year. The type is one of the most useful undershrubs we have, the crimson color of its stems, especially in winter, being particularly bright and cheerful. We do not succeed with the Dogwoods of America. *C. florida* we know chiefly from descriptions and pictures of it, for it does not flower here.

STEPHANANDRA FLEXUOSA, a monotypic genus allied to *Spiræa*. It was introduced from Japan to St. Petersburg by

Maximowicz some twenty years ago, but has been known in commerce only about seven years. It is hardy, deciduous, and has slender, flexuous branches with deeply cut leaves, which are pubescent beneath. The flowers are small, white, and are borne in large, loose terminal panicles. Altogether the plant is sufficiently striking to find favor as a hardy border shrub.

ALNUS TINCTORIA is a new Alder remarkable for the size of its leaves, which are about six inches long and broad, the

crimson. This plant is said to develop its color only when grown in pots under glass.

The summer bedding in the principal parks and public gardens in the neighborhood of London is this year unusually good. The year has been unfavorable in regard to weather, cold, sunless and wet days having been far too frequent to suit this kind of gardening. In spite of this, however, there are many successes and not a few of more than ordinary beauty. Hyde Park devotes a long stretch of ground bordering Park

Fig. 58.—*Cornus Baileyi*.—See page 464.

edges biserrate and the color a rich green. It is probably Japanese.

ACER COLCHICUM RUBRUM has Ivy-like foliage, which, when young, is colored rich crimson-brown. It grows quickly and forms a good-sized tree. It is one of the most attractive of the larger ornamental-leaved Acers.

Other noteworthy exhibits were *Styrax Japonica*, in fruit; *Cydonia Japonica Moorloosii*, which has the richest colored flowers of all the forms of this plant; *Daphniphyllum glaucescens*; *Salix laurifolia*, with large, glossy, dark green foliage, and *Ligustrum lucidum tricolor*, with large oblong leaves colored bright yellow and green, and when young tinged with

Lane entirely to summer bedding, which is always worth seeing and is especially good this year. The beds are very large, in shape either round or oblong, and they are separated by long sweeps of green turf, of which a wide strip runs from one end to the other. At intervals along this there are perfect specimens springing from the turf of Phormiums, Phoenix, Livistona, Bamboos and masses of Purple-leaved Canna. These prevent anything like monotony, and are, moreover, a very attractive feature in themselves. In the beds perhaps the most ornamental combinations are mainly due to a liberal use of Fuchsias of all kinds. Some of the beds are entirely filled with big half-specimen plants covered with flowers, and car-

peted with Mignonette, Iresine or Oxalis. Specimen Fuchsias, Heliotrope, Plumbago and Ivy-leaved Pelargoniums are grouped about on the lawn near the trees with excellent effect. An enormous bed is entirely filled with well grown specimens, four feet high, of pink-flowered Ivy-leaved Pelargoniums, with a few plants of variegated Maize scattered amongst them, the ground being hidden by a blue-flowered Viola. An edging of a narrow-leaved, elegant, variegated Coltsfoot Grass heightened the effect of a massive bed of crimson-flowered Begonias. Adrien Robini is an erect, glossy, crimson-brown Canna of great value for this kind of work. Chrysanthemum Precocité entirely fills several large beds, and proves itself a first-rate bedding plant. In another place there is a round bed twenty-five feet across filled with *Musa Ensete*, *Eucalyptus globulus* and Castor Bean, margined with a massive broad band of *Funkia Sieboldii*. Another bed of the same size is planted with the crimson Castor Bean and *Abutilon marmoratum*, edged with Silver-leaved Pelargonium and blue Lobelia. *Erythrina Crista-galli*, bordered with *Funkia grandiflora*, is an excellent piece of gardening, the vigor of growth and wealth of flower being perfection. Visitors to this park should not miss the fine piece of natural gardening on the east end of the Serpentine. The grouping of the trees and shrubs, the sweep of lawn, the planting of the stream border, which runs from the foot of a cascade—in short, the whole arrangement being delightful; wild rabbits and wood pigeons feeding quietly on the lawns add considerably to the naturalness of the effect. Large specimen Palms, Bamboos, Musas, Strelitzias, Cordylines and Tree-Ferns are tastefully arranged amongst the permanent shrubs.

Regent's Park is quite as good in its way. The most attractive beds are filled with *Celosia pyramidalis*, about a yard high, with heads of flowers as large as those of the Pampas Grass, and varying in color from pale yellow to deep crimson. Nothing could be more beautiful, the habit of the plant is so elegant and the colors so dazzling. These plants are raised from seeds sown toward the end of April, and they are grown under glass until they are in flower, usually about the end of July. They are then planted in the beds, and they continue in beauty until severe frost comes to cut them down. Cockscombs are similarly grown and bedded. The borders and beds generally in this park are finer, more tasteful in arrangement and better grown than I have ever seen them.

The same may be said of Hampton Court. One of the most attractive beds there is filled with a Begonia called Worthiana, which is by far the best bedder amongst tuberous Begonias. It is dwarf, forms a large tuft of branches with narrow foliage, and is heavily laden with bright scarlet flowers, which in form resemble those of *B. Boliviana*.

Cultural Department.

Notes on American Plants.

Hibiscus militaris (the Halberd-leaved Rose Mallow) begins to bloom later in the season than the common swamp Rose Mallow (*H. Moscheutos*). It is a smoother plant, with divided leaves, and its flesh-colored flowers are a little smaller than those of the other. Its natural home is on river-banks, while the other grows in marshes along the coast. But both do finely in ordinary garden soil, come into flower at a season when they will be most appreciated, and are always admired by lovers of flowers. Now that the Hollyhock disease is becoming so widely distributed, these Mallows, which seem to be less liable to attack, ought to become better known.

Gentiana alba (Whitish Gentian) is a fine native perennial for cultivation. It is rather rare, however, and difficult to obtain in large quantities. In Gray's "Manual of Botany" it is described as much earlier than the common closed Gentian (*G. Andrewsii*); but with us in cultivation there seems to be little difference in its time of flowering. The nearly white flowers are open, and in a thick cluster at the summit of the strong, erect stalks. It is a more southern species, and is very rare in New England, if indeed it is found there at all.

Aster corymbosus is one of the common species of wild Aster, which is useful for planting in dry, shaded localities. It is a low-growing species, seldom two feet high, and bears an ample, but loose, corymb of purple and white or yellow and white flowers an inch wide. The leaf is much like *A. cordifolius* in shape, but the zigzag stem is quite different. It is one of the easiest species to transplant.

Aster puniceus is one of the tallest species we have, often over six feet high, and bearing an abundance of its large, showy, violet-purple, or sometimes nearly white, flowers, over

an inch wide. There are varieties of this, smaller plants, with much inferior flowers, but in the true type the largest plants make a fine display when in bloom. It seems to prefer cool locations and a moist or wet soil.

There is a fine display of Golden-rods now in flower. *Solidago lanceolata*, with long narrow leaves and flat heads of small yellow flowers, is one of the earlier species. It seems to prefer moist banks. *S. latifolia* (Wide-leaved Golden-rod) has broadly ovate leaves and a zigzag stem, about two feet high, and bearing numerous pretty bright yellow flowers. Its wide and abundant foliage is of a dark shade of green, and contrasts well with the flowers. Another pretty plant is *S. puberula*, of sandy plain land, growing from one to three feet high, and bearing a dense, prolonged panicle of pretty yellow flowers. Another interesting species growing in cool peat bogs and on mountain-sides is *S. uliginosa*. Its stout stems are not rarely four feet high, and the long head or panicle of yellow flowers varies from six to eighteen inches in length in the largest specimens. The Sweet Golden-rod (*Solidago odora*) in its general appearance differs little from many others, but its leaves when crushed give a pleasant odor and an agreeable flavor when eaten. All of these are easily transplanted in early autumn, and do well in any ordinary garden soil.

Our native perennial Sunflowers are an interesting genus of plants, most of which are in flower about the first of September. There are nearly sixty species and varieties in North America, and no doubt many which have never been in cultivation are valuable for this purpose. *Helianthus giganteus*, one of the tallest, has rough and hairy stems, three to ten feet high, and numerous good-sized, pale yellow flowers. It does well in a light loamy soil, though its natural home is in wet, swampy land. *H. divaricatus*, in favorable localities, is a pretty plant, but in dry and barren soils, where it is sometimes abundant, it is not showy. Its height is from two to four feet, according to the soil from which it comes. Its flowers are good-sized and bright yellow, two inches or more wide. It is not so handsome or valuable a plant as the *H. discoloratus*, which has larger and more numerous leaves and flowers.

F. H. Horsford.

The Hardy Flower-Garden.

THE bedraggled appearance of the borders after a wet period, already reminds us that it is time to prepare for the next year's display of perennials. Where annuals have been used to any extent in the flower-garden, one now realizes more fully the ephemeral nature of their beauty, and determines that for the future they shall take a secondary position to plants of a more enduring character. It has already been noted that Narcissi are best planted at once, and the earlier the better. The same remark also applies now to all the members of the Lily family. To one who is just starting out to grow Lilies, the lists usually found in catalogues are long enough certainly, too long perhaps for a beginner, for many of the sorts included should never be planted by those who have not already had experience with this fickle genus. The list of Lilies which I have found to thrive perfectly in the climate of the eastern states would include *Lilium Batemaniae*, *L. Hansoni*, *L. candidum*, *L. croceum*, *L. pomponium*, *L. tigrinum* and varieties, *L. umbellatum*, *L. elegans*, also known as *L. Thunbergianum*, all the varieties of *L. speciosum*, often called in English lists and periodicals *L. lancifolium*, and, of course, *L. superbum*, and *L. Canadense*, with its pretty varieties. Every one should also try *L. auratum*, but no one should have great expectations of its longevity; I have yet to see the place where this gorgeous Lily has become established. In conversation with a large Lily-grower the other day he said, "To keep *L. auratum* raise your bulbs from seed." But this does not give much encouragement to plant the fine bulbs that are annually imported from Japan, which I have never known to increase in size.

There are other things which should be planted at once, such as *Mertensia Virginica*, one of the most beautiful of native plants, which will succeed in any soil. The Trilliums, too, are now offered and should be planted at once. Try them in shady places where other things do not thrive, but remember that they die down early in summer, and give place to something else, which may be planted along with them. There are many Trilliums, and some are not showy or desirable for garden purposes, but *T. grandiflorum*, *T. stylosum*, *T. ovatum*, and *T. sessile*, var. *Californicum*, are sure to please. Those who have not tried *Camassia Cusickii* certainly should; but remember to plant it deep. It is the best of the Camassias, but *C. esculenta* and *C. angusta* are both good border bulbs that need no coddling. Dodecatheons are now coming to the

front as garden plants, and they include the most beautiful plants of the Primula family that North America can show. The Dodecatheons are sold under a variety of names of garden origin ; but all are worth growing, even the poor, pale form of *D. Meadia*, now so often seen. Those who have not tried planting broken charcoal among the roots of Dodecatheons

so planted last fall was a brilliant spectacle this spring. There is a host of varieties of this fine plant, but none can surpass the type, judging from a dozen varieties we have tried.

German Irises are best planted now, and they will obtain quite a hold in the new soil this fall and flower stronger and better next year for the change. Starved-out old clumps of this fine old

A Feathered American Elm.—See page 462.

should do so ; it is said to deepen the color of the flowers several shades. *Primula Sieboldii*, one of the few really hardy Primulas, may now be planted with the roots near the surface. Strictly speaking, they are rhizomes and should not be covered more than an inch deep ; they need a good mulch of well-rotted manure, which may be left on in spring. A bed

Iris are too often to be seen in gardens. A pretty harbinger of spring is *Adonis vernalis*, whose bright yellow flowers are pleasing when there are few other than bulbous plants in bloom. It should be planted now. Alstroemerias come to hand in the fall, mostly from Holland, which is, by the way, about the only place where one can obtain these most ornamental

and useful of hardy plants. They should be potted as soon as received and placed in a cellar until spring, when they may be set in their permanent positions out-of-doors and become established so as to take care of themselves in future. It is not safe to trust newly imported plants of *Alstroemerias* to the severity of a New England winter, and the same may be said of the *Hellebores* which are thrust upon us at this season. These would speedily die if planted out when received. They must be protected in frames or in pots, and planted in spring. Afterward they can take care of themselves if a little mulching or covering of straw is placed about them.

The first frost will kill the tops of herbaceous *Pæonies*, and after that is the best time to lift and divide them or to procure new ones, remembering that *Pæonies* are, or should be, planted to stay, and the richer the soil is made the better the results will be in years to come. No garden should be without a few of the better named kinds, and those of French origin appear to be the best as a rule. Those who enjoy really good border flowers for cutting should try the *Trollius*. There are several species in commerce; the best of which are *T. Europæus*, *T. Asiaticus* and *T. Japonicus*. All three are distinct, and valuable for cutting. The flowers resemble huge Buttercups of a globular outline, which gives them their common name of Globe-flowers. They need a rich, moist soil.

I have found *Anemone Apennina* perfectly hardy, and it produces a charming blue flower, which opens early in April; but it takes two years to become well established. *A. blanda* is highly spoken of. It much resembles the Apennine Wind-flower, but blooms much earlier. *A. fulgens* I have known to live out all winter and flower gorgeously in spring. It is perfectly hardy in a cold frame, and is also fine for pot culture. These three *Anemones* are tuberous-rooted species, and may be procured now, as may the English and Spanish Iris, both of which are of the bulbous section known as *Xiphion*. These are rather fickle out-door plants, and ought to be wintered in pots in cold frames, and they will then flower beautifully in the border in May and June. In sheltered situations and more favored localities, both the *Anemones* and *Xiphions* would be fine garden plants.

If one has a corner of the garden where Grass or other things refuse to grow, Lily-of-the-Valley will thrive and is a good investment. If the bed is well and liberally prepared, they speedily take hold and thrive, and spread amazingly, where most other things fail. And, finally, every one should try the lovely native *Cypripediums*, and this is a good time to begin. Good, well-ripened crowns can be easily obtained and should be planted in a moist, shady place in rich mould. These Lady's Slippers also succeed well under pot-culture, and will do so year after year. *C. pubescens*, *C. parviflorum* and *C. spectabile*, with the lovely western *C. montanum*, with its raceme of sweet-scented flowers, are the showiest and best to grow. *C. candidum* and *C. arietinum* are both small, and *C. acaule* generally difficult to manage where it is not possible to imitate the natural conditions under which it grows.

South Lancaster, Mass.

O. O.

Notes on Shrubs.

Gordonia Altamaha (*G. pubescens*) is flowering in the Arboretum, the first blossoms opening about September 8th. The plant here requires covering in winter, but it is in a too exposed and rather unsuitable position for one of its kind. There are doubtless many sheltered gardens and nooks in the city of Boston and vicinity where it would survive our winters without protection and eventually become a good sized shrub. We are unable to grow the great evergreen or Laurel *Magnolia* of the south, but this *Gordonia*, or *Franklinia*, as it is often called, seems of a hardier nature, and is well worth a trial in favorable places. Our seasons are so short that the later flower-buds do not develop into blossoms unless protected from early autumn frosts; but, in any case, enough flowers are produced to fully repay the little care given to it and the space it occupies. The beautiful, pure white, delicately fragrant, single *Camellia*-like blossoms expand three inches across, and the cluster of stamens within is bright yellow. The corollas do not persist long, however, and usually become detached and fall thirty-six or forty-eight hours after expansion.

Clerodendron trichotomum is another shrub which in this latitude would be worth growing in sheltered situations, and would well repay any care given to it. This is a Japanese plant belonging to the *Verbena* family, and although it is a good many years since it was introduced into Europe it is still very rare in this country. In this climate the stems are

often so severely injured in winter as to seriously affect the blossoming. Last winter being less severe than usual, the branches were but slightly injured, and they now bear numerous cymes of sweetly fragrant flowers. This *Clerodendron* in its native habitat is a large shrub or sometimes a small tree. The branches are round, smooth and stout. The leaves are usually large, ovate, or sometimes cordate, pointed and more or less pubescent on both surfaces. When bruised they exhale a heavy and rather disagreeable odor. At a little distance the foliage resembles that of a small-leaved *Catalpa* more than any other familiar plant. The flowers are borne in large, much branched cymes on the ends of the branches. The blossom is white or sometimes slightly rosy colored, and expands about an inch across, and it bears four stamens and a slender pistil, which protrude about an inch from the mouth. The narrow, very slender tube of the corolla is about an inch in length, all the lower portion being enclosed in a loose, five-angled, purplish red calyx, which adds much to the showy effect of the flower, and which is conspicuous when enclosing the unopened buds as well as after the corolla has fallen. The flowers of a cyme open here in gradual succession, beginning about the first week of September. It is said that in Japan this plant grows high up on the mountains, and in rich soils produces panicles of flowers eighteen inches or more in length. It is possible that by getting seed from the extreme northern limits or the highest altitudes where this species grows, we may secure a race better able to withstand the severity of New England winters. Besides propagation by seeds, which will hardly have time to ripen in this latitude, this *Clerodendron* may be increased by cuttings from the shoots or roots.

An interesting plant for gardens is a *Clethra* from the southern states, to which Lamarck, in his "Botanical Dictionary," gave the name of the Cottony *Clethra*, or *Clethra tomentosa*, a name which was preserved by De Candolle in his "Prodromus" and kept up by Loudon and other early writers, although reduced to the rank of a variety of *C. alnifolia* by Michaux. It is a hundred years since it became known in European gardens. Later botanists, however, seem to consider it as but a mere form of the common Sweet Pepperbush (*C. alnifolia*), and we look in vain for any reference to it, either by name or description, in the last edition of Gray's "Manual." In some of the earlier editions of the "Manual," however, it is stated that "in the southern states are varieties with the leaves rather scabrous and pubescent or white-downy beneath."

Although the pubescent variety, which the earlier botanists knew as *C. tomentosa*, may not be entitled to specific rank in the botanical classification of to-day, it is, nevertheless, sufficiently distinct in the estimation of the horticulturist to merit some name which would indicate a difference from the ordinary typical *C. alnifolia*. In cultivated specimens in the Arboretum the leaves are larger than those of *C. alnifolia*. They are rugose above and densely covered with a grayish white tomentum beneath. In typical *C. alnifolia* the leaves are more smooth above and smooth and light green in color beneath, being quite destitute of any pubescence or hairs. The individual flowers as a rule are nearly twice the size of those of *C. alnifolia*, and they differ also in that the petals assume more of a bell shape and do not spread out so widely. The slender, pointed, terminal racemes of flowers average considerably larger, and many of them are supplemented by three or four well developed, but smaller, racemes, which, springing from the side near the base of the central one, come into bloom later than it does. To the horticulturist, however, the most important character lies in the time of flowering of the plants. Growing side by side in cultivation and under exactly similar conditions, the first blossoms of *C. alnifolia* open in the last days of July (July 22d in 1889 and 31st in 1890), while the first of those of what we may call *C. tomentosa* do not appear until three weeks later (August 12th in 1889 and 19th in 1890), by which time *C. alnifolia* is past its best flowering, although in woods and other cool places it is found much later. The latest buds of the tomentose variety are not expanded by the middle of October, so that they are usually destroyed by frost, and fruit is never matured. As this tomentose *Clethra* is only recorded from Virginia, Carolina, Alabama and other southern states, it is naturally not so hardy as our northern one. The flowers are quite as fragrant as those of *C. alnifolia*. On account of its extreme lateness in blossoming, this southern variety, or form, as it may be, seems likely yet to become recognized and valued by gardeners at least, and to find a place in every garden where shrubs of this class are prized.

Arnold Arboretum.

J. G. Jack.

Phajus Humblotii.

AMONG the representatives of the genus *Phajus* this charming species must be considered as standing in the first rank, and as a fitting companion of the handsome *P. tuberculosus*, already noted in these columns.

P. Humblotii (often erroneously spelled and called *Humboldtii*) is only just beginning to be known in Orchid collections, through importations from Madagascar last year by F. Sander & Co. The first appearance, however, of this species was in the year 1880, when only a few plants were imported through the agency of a young French traveler, Léon Humblot, whose name Reichenbach attached to the plant by way of commemoration. It is a somewhat difficult plant to get at in Madagascar as well as to import successfully, hence the lapse of nine years between the first and second installment.

The small, pear-shaped pseudo-bulbs have two or three rings around them, and are furnished with a few large, stalked, oblong-acute plaited leaves over a foot long and three or four inches broad. The stout, erect scape rises from the base of the pseudo-bulb and will bear as many as twenty flowers, which are individually about two and a half inches across vertically. The flowers appear in April and continue until the middle or end of July. I do not mean that one spike of flowers will last this length of time; but where there are several plants, each opening at different times, flowers may be seen for three or four months. In May last I saw nearly two hundred spikes with flowers expanded, and a very charming sight they presented. The ovate-acute sepals and petals are of a soft rose color, sometimes mottled with white; the large spurless lip has a nicely frilled rosy front lobe, and reddish brown spots thickly covering the pale yellow side lobes, while the bright yellow, saddle-shaped callus presents a striking contrast to the surrounding colors and immediately attracts the eye.

One variety is already known—viz., *P. Humblotii alba*, originally known as *P. Henryi*. This is distinguished from *P. Humblotii* proper in having pure white sepals and petals, and the colors on the lip less deep in tone.

The natural surroundings of *P. Humblotii* are malarial marsh-lands, where it grows at the base of large trees, according to its discoverer, Monsieur Humblot, with plenty of heat and moisture. An imitation of these conditions as nearly as possible (with the exception of the malaria) seems to be the best way to treat this plant in cultivation. A warm, moist house, with as much diffused light as possible, suits it admirably; the soil may consist of rich fibrous loam and leaf-mould, and pots, which appear to be most suitable, should be well drained. The plants rest a little during the winter months and require but little water; with the approach of spring, however, the young shoots push forth, and the quantity of water must then be daily increased to make the plants grow vigorously and develop their flower scapes.

London.

John Weathers.

Allamanda Schottii.—One of these vines occupies part of the roof on the west side of the plant-house here, covering 200 square feet. It is planted in a box three and a half feet long and two and a half feet wide and nine inches deep. The soil is a rich loam, and ordinary stove temperature is maintained, and in summer the plant is shaded from strong sun. With plenty of moisture in the air and water at the roots constantly, it never flags. A few applications of liquid manure when the box is full of roots, or a mulching of rich compost, is given, according to its needs. Being so strong a grower, it would soon have a starved look, and would produce smaller flowers with less generous treatment; as it is now, we have an average of 500 flowers open daily, and have had not less than 10,000 flowers this summer, averaging six inches in diameter.

Dongan Hills, Staten Island.

W. Tricker.

Dipladenia atropurpurea is an easily grown, free-flowering species, with trumpet-shaped flowers as large as those of the old *D. Boliviana*, but broader in the tube than that species, whilst the color is deep velvety crimson, except toward the base of the tube, where it is deep rose. This plant is almost forgotten now, but fifty years ago it was a popular stove-climber. Messrs. Veitch introduced it from Brazil, and it was awarded the Banksian medal as a new plant. Sir Joseph Paxton grew it at Chatsworth in combination with *Stephanotis*, a happy idea. The flowers last at least a week. It has been reintroduced by accident, a tiny plant having been imported along with a mass of *Cattleya* two or three years ago. It is now flowering at Kew. Other names for it besides the above are *Echites atropurpurea* and *Dipladenia violacea*.

Cyperus Natalensis.—A plant bearing this name has lately found much favor here among growers of decorative plants

for market. It forms an elegant tuft of smooth, shining, bright green, channeled, arching leaves from two to three feet long and erect scapes four or five feet high, bearing flower-heads similar to those of *C. alternifolius*, but larger. It seeds freely under cultivation. Grown in a moist, warm house, it soon forms a handsome specimen. It is a gross feeder, and thrives on frequent doses of manure. The value of the plant is in its fitness for decorative work and its sturdy constitution. It keeps its healthy green color for months in an ordinary dwelling room. According to Mr. Clarke, of Kew, it is certainly not *C. Natalensis*, but a *Mariscus*, allied to, if not a variety of, *M. sparganifolius*.

Kew.

W.

Grand Mogul and Jean Soupert.—While quite similar in habit and flower these two Roses are not identical—Jean Soupert was sent out by La Charme in 1875, and proved a very effective dark velvety Rose; Paul's Grand Mogul, of a recent year, is a seedling from A. K. Williams, and is a grand variety as seen in England. Neither of these three fine Roses does well in our country, probably on account of a lack of constitution to withstand our trying summer's sun; but wherever a grand, velvety crimson rose of the darkest and richest shade is desired our Rose-growers should plant Jean Liabaud; here we find freedom of growth, boldness of foliage, a rugged constitution and a flower once seen never to be forgotten—black and crimson displayed in a texture of velvet.

La France and Duchess of Albany.—Duchess of Albany is a sport from La France, and, while they have their resemblances, they are quite as distinct as Pearl and Sunset. By selecting a La France deeper in tint than the average and a Duchess lighter than its average one might hold in his hand two very similar Roses; but when the two are seen in a mass in any florist's forcing-house the most casual observer will note the new variety with admiration. They are quite similar in constitution, Duchess of Albany being the less liable of the two to drop its leaves; its bloom is slightly larger, too, under the same cultivation, while the color is a deep even shade of rosy pink without the light satiny sheen seen in La France. A dozen buds of Duchess make a cluster as distinct from a similar cluster from La France as a dozen buds of Catherine Mermet would be. Duchess of Albany is already highly appreciated among the florists as one of the most popular and most easily managed of the newer forcing Roses.

Richmond, Ind.

E. G. Hill.

[These notes from Mr. Hill were called out by the statement in an English journal that the Roses Grand Mogul and Jean Soupert are now recognized as the same, and that it would probably be proved that La France and Duchess of Albany were also identical.—Ed.]

Kniphofia (Tritoma) Corallina, just out of bloom, is one of the most desirable of the Torch Lilies or Red-hot-poker plants. It blooms freely for several months, and the flowers are most attractive, of a bright coral or orange red, without the clear yellow color on the lower side as in *K. Macowanii*, from which this is said to be a seedling. The plant is some five feet high and has a more spreading habit than the parent. Kniphofias cross so freely that it is interesting to raise seedlings from a collection, as many variations can be secured. *K. Corallina* bloomed this season from seedlings of 1889, quite in contrast to *K. Saundersonii*, which required three and four years' growth.

H. multiflorus, fl. pl., the double Sunflower most common in cultivation, is an excellent garden plant for a large border, vieing as it does with the African Marigold in bold effect of flower. It should be divided frequently, and unless grown in good soil the plants are much dwarfed. The perennial Sunflowers are all subject to attack of white mildew at this season and need attention with sulphur.

Helianthus lætiflorus follows closely in bloom *H. rigidus*, and is one of the best of native single Sunflowers. The habit is very neat, and the plant is about four feet high, producing a plentiful supply of deep yellow flowers of firm texture and some four inches in diameter. The disc of this species is yellow, or rather the purple base is covered with yellow anthers, which is the chief distinction between this and *H. rigidus* (the Prairie Sunflower), sometimes known as *Harpalum rigidum*, the disc of which is deep purple. The latter variety is also an earlier bloomer, coming on in July and August. A variety received as *H. Japonicus* is very slightly different from *H. rigidus*, to which it is inferior. A lot of seedlings from *H. rigidus* are decidedly inferior to the type; of a distinctly lighter

color, and, curiously, have less of the rambling tendency at the roots so characteristic of both of the above named varieties. They are both propagated by underground stolons, which ramble in all directions; and as the old stool dies annually one not familiar with this habit would conclude early in the season that the plants were lost. They are perfectly hardy, however, though disliking too much wet.

Helenium autumnale.—This showy yellow Composite is daintily sketched by Mr. Gibson in the current number of *Harper's Magazine*. It is so seldom seen in cultivation that attention should be called to its beauty and merits as a plant for the back border, where in August and September its many-branched heads of golden yellow flowers are very bright and attractive. The plant is a vigorous grower, four to five feet tall and a profuse bloomer. The individual flowers are from one and a half to two inches in diameter, entirely golden yellow, with a round button-like disc, from the lower half of which the flat, blunt petals slightly droop. Like many of our native plants, this Sneezewort is more appreciated abroad than at home. A dwarf variety is offered as *H. pumilum*, which is said to be an improvement on the type. My plants are seedlings from this variety, but apparently not true, as they differ little from *H. autumnale*, except in being somewhat improved in cultivation.

Desmodium penduliflorum, now in bloom, is one of the most graceful habited of hardy herbaceous plants, with a beautiful combination of flowers and foliage, though quite unattractive earlier in the season, when the leaves have an ugly habit of folding together in all dry spells. The flowers are a bluish red, but even with this drawback the plant is well worth growing for its distinctness and contrast to the usual showy autumnal flowers.

The Forest.

Preserving Small Forests.

THE greatest obstacle in the way of securing efficient action for the preservation of the public timber-lands arises from the lack of personal interest in the work. The public forests are spread out over a wide extent of territory; their character and condition are only partially known to the mass of those living near them, while the bulk of the people resident at a great distance from them know hardly anything about them and feel little interest in them. It is only the comparatively few who take broad views of things and feel that what concerns the public concerns them, and so are ready to make the public interest their own.

In the case of private forests there is no lack of personal interest. But the difficulty here is that the interest is so limited in duration that there is no adequate motive for a proper forest-management, while the limited extent of individual holdings usually prevents any such continuity of woodlands as will secure the best forest-results. Our system of land-tenure is such, and the habit of the people such, that any parcel of land may pass into the possession of a new owner at any time. The prospect of pecuniary gain or relief from a pecuniary exigency, however temporary, is enough usually to occasion the transfer of land from one to another, and most land-owners in this country hold their lands in the consciousness of such uncertain and limited tenure. Of course, the motive for planting or properly caring for woodland is correspondingly weak. Then, also, the length of time requisite to bring trees to their maturity operates as a discouragement to effort or outlay in planting or managing forests. The planter stands dismayed before the slowly rounding cycles of the Oak or the Pine. If we had a system of entails it might be different. Then one would feel that though his own life might soon come to an end his efforts and expenditures on his estate would not be wasted, but would accrue to the benefit of his family, his children and his children's children.

What is needed in our country, therefore, for the most successful dealing with trees in masses, with forests, is a personality whose life is as lasting as that of the trees themselves. The nation is such a personality. It lives on without any assignable or necessary limit to its duration. Hence the nation or state can care for the forests in the best manner and use them to the greatest advantage and with the highest profit in all respects, as is seen by the forest-management of European countries. So, also, there are lesser communities having such an unlimited duration of life, such as counties, towns, parishes and precincts. So, likewise, there are various corporations created by law which have no necessary limit to their life. Trust companies and guilds of many kinds are such. They can properly undertake any enterprise, no matter

how much time it may require for its accomplishment. To such an unlimited life to grow a forest, even of Sequoias, is no more than for an ordinary person to grow a crop of Corn.

Why may we not avail ourselves of this larger, longer life for the establishment of forests something like the communal forests so frequent in Europe? While encouraging every farmer and land-owner to preserve a portion of his existing woodland and to plant shelter-belts, at least, why may not our counties and towns as such establish and maintain forests? In many of our counties and in many of our towns there are tracts of land, sometimes of large extent, often comparatively small, but many in number, which are unfit, perhaps, for ordinary cultivation, because they have a stony soil or are swampy and not easily drained, or lie upon steep hill-sides. As they are now they do not yield more than enough to pay the taxes assessed upon them. But while thus unprofitable in their present condition they could all be profitably used for the growth of forests; and why should not the county or the town—that is, the whole people in their corporate capacity—utilize such tracts by taking them out of their present unprofitable condition and devoting them to a remunerative forest-growth? In many cases such tracts would be given to the county or the town; in any case they could be bought at a very low price. Where there are several small patches of woodlands, or lands partly wooded, but separated from one another, these isolated wood-lots are useful now only for their small yield of fuel and inferior timber. If they were in the possession of the county or the town they could be combined, the necessary connecting land also being taken, so as to form such a continuous stretch of woodland as to possess more or less of the qualities of a forest, exerting climatic and other influences. Such a forest would also warrant better management and be more productive than smaller parcels. From time to time, also, the county or town could extend this forest-area by gift or by purchase, as the private person adds to his land, and as is done, in the case of their larger forests, by the European states.

Another advantage which would be gained by the town or county forest-system would be the more efficient protection of such forests. They would be protected from fire and other injury as no strictly private forest or forest belonging to the General Government would be; for the whole community would have an interest in watching them as their personal property; for every citizen would be an owner, and if fire should by any chance break out in such a forest, every one would be prompt to assist in extinguishing it.

Such forests could be cared for and maintained at a minimum of expense and a maximum of profit. This would be as the result of the general law, that a large business is more economically managed, proportionally, than a small one. The proprietor in this case, the town or county, or trustees or other corporate person, would always be able to command the requisite labor at the proper time. The work would be done under no such stress for immediate results as often urges the private land-owner; therefore the work would be done the more cheaply. If an existing woodland or several tracts were thus taken in hand, the necessary thinning could often be secured with little or no outlay of money.

There can be little doubt that a fair rate of interest on such an investment as this could be secured. Examples of the management of such limited and local forests abroad indicate this very plainly, while the sanitary influence upon adjacent agricultural lands would also properly be taken into account, and their general climatic effect, whenever they were of considerable extent.

Such forests would also incidentally become valuable as experiment stations, where many kinds of trees would be tested on whatever varieties of soil and exposure the grounds might furnish, and thus every landholder around might learn much as to what trees it would be most desirable for him to plant on his own premises.

A nursery would also, naturally, be a part of the equipment of such a forest, for the purpose of rearing trees to fill the places of those cut from time to time. And this might easily be made a source of revenue, by the sale of young trees to the land-owners of the town or adjacent region.

Finally, such a forest might have a value over and above any of a pecuniary kind, by being made a place of pleasant resort for the whole community—a place of special meetings on various occasions and of healthful recreation at any time. Thus the people would cultivate their forest, and it in turn would cultivate them, developing in them a taste for natural objects, opening their eyes to new beauties and new sources of delight, dwelling them together in society and endearing to them their dwelling-place more and more with the passing years.

Correspondence.

Some Northern Ferns.

To the Editor of GARDEN AND FOREST :

Sir.—The rarer Ferns found sparingly in the northern limits of the United States, but more generally in the eastern provinces of Canada, are generally away from the beaten tracks of tourists—amid mountain glens, in the neighborhood of waterfalls or nestling quietly on shaded cliffs above the reach of any but the most venturesome climber. The pretty little *Asplenium viride* is exceedingly rare. I have only met with it in the neighborhood of St. John. Here it is found in comparative abundance, in some half dozen places, hiding in the clefts of limestone rocks, and defying any but the most Fern-loving eye to discover its retreats. A few friends who have occasionally accompanied me to my “preserves” have been successful in its cultivation, and I have never seen it more beautiful even in its native haunts than it appears in a dainty dish in a friend's house. Two years ago the plant was set in a moderately deep glass dish with the small amount of earth which was gathered from the cleft of rock in which it was found growing. An occasional spraying of rain-water, with care to drain off the extra moisture that had gathered in the dish, is all the attention it has needed.

Pellaea gracilis I have seen only in the northern part of New Brunswick, in the neighborhood of Grand Falls and Woodstock and one or two of the tributaries of the St. John River. I shall never forget the sight that once met my eye on a projecting ledge of that most beautiful of New Brunswick rivers—the Madawaska. Growing from the clefts of rocks, and lifting up its delicate, pale green fronds on the grassy slope of the bank in the greatest profusion and luxuriance, the whole spot of wonderful green could have been covered by my umbrella. I had never seen the Fern before, and I have seen it but once since, but that exquisite little picture in the wilderness, with surroundings in perfect harmony, is a joy forever.

Scolopendrium vulgare is found in one locality in New Brunswick, but just where is unknown to me. Ten years ago the gardener of Mrs. Charles Connell, Woodstock, discovered the only specimen that has been seen in New Brunswick. A few Fern-lovers have searched diligently for the coveted prize in all the shaded ravines for miles around, but as yet without success.

A few weeks ago a party of adventurous students of the Nova Scotia Summer School of Science started one morning to find Moose River Falls in the recesses of the Cobequid Mountains. Adventurous, I say, because only one lady had ever visited the falls before, and here were at least twenty accomplishing the feat of scaling mountain heights, toiling through ravines, to catch a glimpse of one of the choicest bits of scenery to be found in eastern America. The Moose River, rising amid the heights of the Cobequid Mountains, acts much like other mountain streams at first, but suddenly makes a series of three or four mad plunges, the last and greatest being a leap of about a hundred feet into a basin in the form of an amphitheatre whose walls of perpendicular rock rise to the height of over 300 feet from the bed of the stream. Far up in the clefts of the rocks could be seen at least one *Woodsia* (perhaps *Ivensis*) and *Aspidium fragrans*, which I had been trying to find for several years and now saw for the first time. It is found in two localities only in New Brunswick, and this was the second for Nova Scotia. Mr. A. H. Mackay found it again a few days after at Minnehaha Falls, another picturesque glen of the Cobequids, along with *Asplenium Trichomanes*, which, although described as common in Gray, has never been found in New Brunswick and but twice in Nova Scotia.

St. John, N. B.

G. U. Hay.

Insect Enemies of Ampelopsis.

To the Editor of GARDEN AND FOREST :

Sir.—The Vine on my house, Japanese Ivy, has been devastated during the past summer by a green worm of considerable size. Many other houses on this street are similarly afflicted. It is gradually becoming a serious pest. Can you suggest any remedy? Is there any liquid application that could now be made to the roots of the Ivy that would kill the creature in its present state?

Beacon Street, Boston.

A.

[In the absence of specimens or more exact information we would say that the injuries referred to are probably caused by the caterpillars of the so-called eight-spotted Forester (*Alypia octomaculata*), an insect which has some-

times caused much disfigurement to the foliage of both Japanese and American species of *Ampelopsis* in Boston and other cities. The moth which deposits the eggs which hatch into the troublesome larvæ expands from an inch to an inch and a half across the wings. It is of a velvety black color, and is marked by eight large conspicuous spots, two on each front wing being pale yellow, two on each hind wing being white. Unlike the great majority of moths these fly in the day-time, and observing persons, when crossing the Boston Public Garden, cannot have failed to notice these insects as they fluttered about the flowers of the dwarf Mountain Ashes, the dwarf Deutzias, the Spiræas and other plants in the latter part of May and in June. Where this insect causes serious injury to the *Ampelopsis* the moths should be caught and destroyed whenever possible. In destroying the caterpillars hand-picking may be tried on small plants. Where hand-picking is out of the question insecticides must be tried. Fresh Pyrethrum powder may be dusted on dry from a hand-bellows made for the purpose, or used in a liquid form by spraying with a strong syringe or a force pump. This insecticide kills by contact, and not by being devoured, and may be used without fear of injury to persons. White Hellebore may be found more efficient, as the caterpillars are poisoned by eating it, and it also may be used dry or in water. In a liquid form this and the Pyrethrum may be used at the rate of a tablespoonful to a gallon of water. Although a poison, the Hellebore is not nearly so dangerous as London Purple or Paris Green would be.

Kerosene emulsions might be equally effective, but these and the arsenical poisons, in inexperienced hands, are liable to injure the foliage, whereas the first two can do no harm to the leaves. The remedies should be applied as soon as the caterpillars are found on the Vines, usually early in July, and they should be repeated if found necessary. The pest cannot be destroyed by applications of anything to the roots of the plant.—Ed.]

Practical Aid for Forests.

To the Editor of GARDEN AND FOREST :

Sir.—Professor W. A. Buckhout's article on “Restoring Wasted Forests,” in your paper of August 20th, is one of remarkable interest and value. All its suggestions are excellent, and if they were heeded there would be little need of forest-tree-planting in the eastern states. The idea of the use of trespass notices is sensible and practical, and along with them a brief educational appeal of fifty or a hundred words, a request and a reason for being careful, printed in large, plain type on some durable material, and fastened to the trees everywhere, would soon have an improving and perceptible effect. There is still a good deal of common sense in the world, and it responds to effort of this kind. To make an enduring and fruitful impression on a community regarding a new subject requires time, and, especially, it requires much repetition, but it can be done by the use of such means, and the sooner we begin the sooner we shall accomplish something.

And now, particularly, I know of nothing else so effective which would cost so little as to reprint this article of Professor Buckhout's in a “slip,” to send to the people who are interested in forestry-matters—or who ought to be—everywhere. We could all use it in our letters, and the distribution of a few thousand copies would exert an influence. It would be doing something, and until we do something we do not improve things very much.

New York.

J. B. Harrison.

The Pepino.

To the Editor of GARDEN AND FOREST :

Sir.—In answer to Dr. Sturtevant's inquiry as regards the Pepo of Peru, I can say it is probably identical with the Pepino of Central America. This *Solanum* fruit is of the size of a hen's egg or a goose egg; tastes like a melon with a very fine acid; allays thirst readily. I introduced this plant some seven years ago, and it has been tried in various parts of the United States. It has only succeeded in Florida, but has there proved of considerable value. It is one of the finest fruits of the highlands or cooler parts of the tropics.

California Academy of Science, San Francisco.

Gustav Eisen.

Notes.

The large, bright red, cone-like fruits of *Magnolia umbrellata* are now very attractive.

While in almost every other part of the country the Apple crop has signally failed, the trees in the mountain valleys of western North Carolina are loaded with fruit.

Monsieur Edouard André, the distinguished landscape architect of Paris, and one of the editors of the *Revue Horticole*, is now in Montevideo, where he has been called to execute some important public works.

From a recent number of the *Anales* of the University of Quito we learn that a new *Acrostichum*, found on Mount Pichincha, in Ecuador, at an elevation of more than 10,000 feet, has been named *A. Yatesii*, after Dr. Lorenzo G. Yates, of Santa Barbara, California.

In our notice of the hybrid *Cypripedium Arnoldianum* last week it should have been stated that Messrs. Pitcher & Manda received for it the silver medal of the Massachusetts Horticultural Society. At the same exhibition a certificate of merit was awarded to the Cambridge Botanical Garden for a fine collection of flowers of one of the night-blooming *Cereuses* (*C. triangularis*).

A pleasant, but rather pathetic, incident that occurred during the meeting of the Forestry Association at Quebec was the visit of the old Huron Chief Sioui and his son in full Indian dress. He was introduced by President Joly, and made the following address: "We are the children of the forest, come to welcome the friends of the forest. I wish you, for my people, joy and success in your good work. When I was a child I lived in the forest; I have always lived in the forest, and I wish to die there. My people are few in number; we are dying away with our home, the forest. Protect us and our home, and you will have the prayers of the Hurons and the gratitude of their hearts."

Perhaps no paper read at the meeting of the Forestry Association at Quebec excited more general interest than one by Mr. Auguste Dupuis, of St. Roch des Aulnais. In this far northern latitude, under unfavorable conditions and at his own expense, Mr. Dupuis has carefully tested almost every variety of tree, both native and foreign, which gives any assurance of success. The results have been carefully noted, and they furnish data that will be invaluable for those wishing to plant trees in the far north. This work has been patiently carried on for many years, and the failures are quite as instructive as the successes. It is the kind of work that ought to be commenced at once at the different experiment stations of the United States.

The annual fruit and vegetable show of the Massachusetts Horticultural Society last week proved an entire success. The vegetables were all of superb quality, and the abundance and excellence of the fruit was remarkable in spite of the discouraging season. One of the most attractive features of the display was the greenhouse grapes from the gardens of Mrs. Lassell, of Whitinsville (Geo. McWilliam, gardener), and Mr. N. T. Kidder, of Milton. Mr. Robert McLeod, gardener to Mr. D. B. Fearing, of Newport, Rhode Island, showed some samples of the Late Crawford peach, which were marvels of orchard-house culture. The extensive collection of miscellaneous fruits from the Massachusetts Agricultural College at Amherst was both interesting and instructive. It would be a good thing if such institutions would more frequently demonstrate their utility in a manner so practical. A rich display of ornamental fruiting shrubs was made by Mr. Jackson Dawson, of the Arnold Arboretum. It represented a host of beautiful and desirable things.

In the Government Crop Report for September the following statement is made by Mr. T. W. Clark, a statistical correspondent for Marathon County, Wisconsin: "The northern half of Wisconsin is one vast berry patch. Strawberries grow profusely in their season; following them comes the Blueberry during the months of July and August, this crop amounting to hundreds of thousands of bushels. Some black Raspberries and a few Service-berries are found. The red Raspberry, Blackberry and Dewberry yield thousands of bushels. Carloads of glass cans are used annually in preserving these for winter use. Thousands of people find occupation in harvesting these spontaneous crops of luscious fruit. The Cranberry comes to perfection in September, rounding out the season. The value of the wild fruit utilized in northern Wisconsin is estimated at \$1,000,000. Three or four times as much goes to waste for want of pickers. The exceeding healthfulness of

this portion of the country may be attributed in a great measure to the purity of the water and the profusion of fruits."

Some time ago we spoke of the fragrant Ferns which New Zealanders used to scent their oils and other articles of food. An English florist, Mr. John Dutton, writing of one of these, *Polypodium pustulatum*, in a local paper, says: "The dry fronds of this Fern, placed in rooms or in books, give off a most agreeable perfume, which lasts for years and greatly resembles the odor of the Heliotrope. This scented Fern, it appears, was held sacred by the natives, who for a long time kept the secret to themselves. It grows in the forests on the west coast of New Zealand, and also in the North Island, but in neither place is it common. One or two varieties are met with occasionally, in one of which the fronds are forked, and in another they are lobed. The perfume appears to be strongest on the sori-bearing fronds. This species was introduced into England in 1820, but has, it seems, quite dropped out of commerce, for we have not found it mentioned in any trade list. It would be interesting to know more about it, and whether, if it is still cultivated in this country, its fragrance is as marked as when growing in its native habitat."

Mr. Watson gives in the *Gardeners' Chronicle* a remarkable instance of tenacity of life in a Yucca. Nearly two and a half years ago the trunk of a Yucca, probably *Y. elata* (see vol. ii., p. 560, fig. 146), was received at Kew from Mr. C. G. Pringle as a specimen for the Museum of Woods. It measured fourteen feet in height by one foot in diameter near the base. There was not a vestige of a root upon it, and the top had been sawn off. It was at once placed in the museum, where, of course, the conditions are almost as dry as an oven. A week or two ago two shoots were seen growing out from the top of the trunk, one composed of leaves, the other of flowers. On examination the whole of the trunk proved to be full of sap and as succulent as if it had only just been dug up from the ground. It was, therefore, removed to the temperate-house, where it may now be seen in flower. *Y. elata* is peculiar to the dry desert region west of the Rocky Mountains, between the United States and Mexico. It has erect, stiff, filamentose leaves, and an erect flower-spike ten to twelve feet high; the flowers are four inches across and pure white.

In a San Francisco dispatch to *The Tribune* it is stated that although this is the best year ever known in California for producers of fruit, the fruit-packers will suffer heavily, because of their contracts to deliver dried and canned fruits for about one-half the ruling rates. Early in the season, when reports came from the east of the total failure of fruit, they discredited those concerning the Delaware peach crop, and made contracts on the usual terms for the delivery of fruit this fall. The result is that they are now paying ten cents a pound for prunes which they have agreed to deliver for five cents. The same rates hold good in regard to peaches, pears and other fruits. One large packing firm will lose \$50,000 on prunes alone, while several smaller ones will probably go under, as they will be unable to stand the losses. It is a great year, however, for fruit-growers, as prices are about double what they usually are and the crop is large. Even grapes, which have been a drug on the market for several years, bring high prices. Ordinary Zinfandel wine grapes fetch \$20 a ton, and large quantities not used for wine have been dried. These will be introduced this winter at the east for stewing and as a substitute for currants.

A month ago we published an account of the famous Holgate Nurseries of James Backhouse & Son in the ancient city of York, and now, with sincere regret, we are called upon to announce the death of the head of the firm. Mr. James Backhouse was more than a nurseryman, for he had inherited a love of botanical science from his father, who, together with his uncle, became the proprietors of the nurseries seventy-five years ago. In early life Mr. Backhouse published a "Monograph of Hieracia," and the close observation which was displayed in that work has characterized his methods of business and study through life. He began to import and cultivate Orchids among the first, and his collectors in various tropical countries discovered many of the best species in cultivation. Besides Orchids special attention has been given at the York Nurseries to the cultivation of Ferns, Conifers, herbaceous and especially alpine plants. The rock garden of this establishment, where these alpine plants are collected and have been cultivated with remarkable success, is one of the best specimens of this class of work, and the plants are very tastefully arranged in the crevices of the immense pile, which rises at times to the dignity of a cliff. Mr. Backhouse was sixty-five years old at the time of his death.

Forest-Fires.

A RECENT Washington dispatch announces that a bill to protect the trees on Government land from destruction by fire has been occupying the attention of the Senate. It certainly is high time that Congress should take some action in this regard, especially since the season is at hand when conflagrations in these forests on the public domain are most common. The law simply provides that any person who shall maliciously or negligently set on fire any woods, underbrush or prairie on the public lands of the United States, or who shall suffer any fire which he may have lighted on other lands to pass therefrom to the public lands, shall be guilty of a misdemeanor, and upon conviction in the District Court of the United States shall be fined a sum not more than three times the value of the property destroyed or injured, or imprisoned for a term not more than three years, or both. When this bill or a similar one was up for discussion a few months ago its constitutionality was questioned on the ground that the General Government had no authority to create any offense in a given state except on lands where it has exclusive jurisdiction. In other words, the United States has no more right to say that it is a criminal offense to burn timber in a given state than it has to say what shall be larceny or other misdemeanor on the public lands in the same state. Of course this denies to the Government the right of protecting its own property, and it is plain that common sense legislators, if they are in earnest about the matter, can devise some enactment which the courts will recognize as authoritative. The real obstruction which stands between these incendiaries and punishment will be, as it has been in the past, a lack of intelligent interest on the part of the people and of a strong public opinion behind any law to insure its enforcement. Until that opinion develops laws will be of little value, but if the time comes when the people of the country realize the value of its forests and their personal interest in them as a part of their inheritance, there will be no difficulty in making laws whose constitutionality will not be questioned by even the most strict constructionist.

In the civilized portions of Europe there is no longer any serious danger from forest-fires, because every one hastens to extinguish them as soon as they are started, and the Government can call out the whole force of the country to assist. But in less highly organized society the forests suffer from fire exactly as they do on our western frontier. From a recent number of *Akhbar*, a daily journal of Algeria, we learn that the Arabs are hardly more civilized than our own citizens. Half a column is filled with the record of a score of forest-fires all raging at once in different parts of the country. In one place 800 acres of Cork Oaks are swept away. Not far from this 5,000 acres more have been devastated. In an adjacent district 3,800 acres of forest are burning, and the woods of the entire province of Constantine are said to be in flames. There is nothing novel in these sweeping conflagrations. The Arab, like our own herder, sets fire to the brushwood either to make a clearing or to encourage forest-pasturage for his flocks and improve his hunting grounds. In 1865 a single fire lighted by a shepherd swept over 4,000 acres. In the three years from 1884 to 1887 more than 1,000 fires were started, which burned over 300,000 acres, and until these people realize the value of the forests to them the entire 7,500,000 acres of standing timber in Algeria must be threatened; and this means the possible destruction of the most important of the natural sources of wealth of the country, to say nothing of its influence upon the climate, and, through the climate, upon agriculture and the general prosperity of the country. Altogether these African Arabs seem to be doing the best they can after their feeble fashion to imitate the robust and exuberant incendiarism of our own people.

It may not be out of place here to recall the fact that fires sometimes destroy forests which have more than an economic or climatic value. Perhaps no forest in the world is more interesting from historical reminiscences than that which clothes the slopes of the Pentelicus Range and overlooks the City of Athens. These groves are associated with the familiar names of the great heroes and philosophers and lawgivers who retired to their shade for rest and refreshment, or to enjoy the prospect over the Bay of Marathon and the Attic plain, and they formed the background to some of the most stirring scenes portrayed in the annals of the world. But a few weeks ago a fire broke out on the heights and raged until the magnificent verdure of this famous forest was literally turned to ashes. A letter from Athens says that the mountain range now presents a pitiable picture of blackened devastation, with barren sides staring down on the field of Marathon. All of Attica above the capital is in mourning for the loss of this sylvan shade and shelter from the sweeping winds; and indeed the civilized world must lament the destruction of a forest intimately associated with so many capital events in the history of the Greek nation.

WE have heretofore given expression to the feeling of regret at the threat of extermination which hangs over some of our beautiful wild flowers, or at least at their certain disappearance from places where they have once abounded. It is unavoidable, where important changes are made in the face of the country by drainage or cutting away forests and by burning over clearings, that many indigenous plants will be destroyed. Where land is needed for agricultural use proprietors will not be careful to save *Trilliums* or *Lady's Slippers*, but it does seem cruel for collectors to gather so many of these plants to sell that they are practically eradicated from localities where they once bloomed in profusion. Other offenders in this respect are certain botanists who gather rare plants for specimens because they are rare. But the most serious attack of all comes from the thoughtless gatherers of flowers, who carry away wild flowers by the armful only to throw them away. We speak of this now because we have just received a descriptive pamphlet from the Secretary of the American Wild Flower Club, which contains an earnest appeal for the preservation of our native plants. We

cannot help feeling that a society of this kind might do much good if properly directed, and the formation of local clubs with the same purpose should be encouraged. It may be that the appeals of this pamphlet are fraught with a trifle more of urgency than the cause demands, but no enterprise of this sort will succeed without the enthusiasm and devotion which comes from a profound conviction of its importance on the part of its promoters. We have no personal knowledge of the working of this club, but all persons who have at heart the preservation of our native flora are invited to address the Secretary of the American Wild Flower Club, Wilmington, Delaware, if they desire more specific information as to its scope and aim.

A Stone Bridge in Wales.

WE give this week on page 479 a picture of another small stone bridge which, in conjunction with those already published, shows the variety in structure and general effect of which such rustic structures are capable. This one, which bears the name of Pont-y-pair, spans a little river at Bettws-y-Coed, in Wales, and, as will be seen, is of the simplest and roughest construction, but, nevertheless, is both stable and picturesque. From the aspect of the river-bed the photograph seems to have been taken at the dry season of the year. When the channel is fuller the look of the spot must be quite different and the sylvan beauty of the view much greater.

A Classification of American Grapes.

GENUS VITIS, Tourn.; L. (in part).

SECTION I. EUVITIS, Planchon.

- SERIES 1. RIPARIÆ (Munson).—1. *V. rupestris*, Scheele. Ozark Hills, Tennessee, to south-west Texas. 2. *V. riparia*, Michx. Rocky Mountains, to Atlantic, north of Ozark Hills, to 55° latitude. 3. *V. Solonis*, Hort. Berol. Headwaters of Red, Canadian and Arkansas Rivers. 4. *V. Doaniana*, Munson. Headwaters of Red, Canadian and Arkansas Rivers.
- SERIES 2. OCCIDENTALES (Munson).—5. *V. Arizona*, Engelm. Western Texas, New Mexico, Arizona, Chihuahua. *V. Arizona*, var. *glabra*, Munson. New Mexico, Arizona, Chihuahua, south Utah. 6. *V. Girdiana*, Munson. South of San Bernardino Mountains, California. 7. *V. Californica*, Benth. California north of San Bernardino Mountains to Rogue River, Oregon.
- SERIES 3. CORIACEÆ (Munson).—8. *V. Champini*, Planch. Cretaceous hills, south-west Texas. 9. *V. candicans*, Engelm. Cretaceous lands, Red River to Rio Grande and into Mexico. 10. *V. coriacea*, Shutt. Central and south Florida.
- SERIES 4. LABRUSCÆ (Planch).—11. *V. Labrusca*, L. Central Tennessee, north-east Georgia, east of Alleghanies to Maine.
- SERIES 5. ÆSTIVALES (Planch).—*V. vinifera*, L. Central and south-western Asia, early carried to Europe, etc. (exotic). *V. Bourquiniana*, Munson. "Southern Æstivalis" traced to southern Europe along the Mediterranean (exotic). 12. *V. Lincecumii*, Buckley. South central Texas. *V. Lincecumii*, var. *glauca*, Munson. North-eastern Texas to Missouri River. 13. *V. bicolor*, Leconte. Illinois, south Wisconsin, Michigan, Indiana, Kentucky, Ohio, New York. 14. *V. æstivalis*, Michx. Tennessee, Georgia, Alabama, North Carolina, South Carolina, Virginia, Indiana, etc. 15. *V. Simpsoni*, Munson. Central and south Florida.
- SERIES 6. CORDIFOLIÆ (Munson).—16. *V. cordifolia*, Michx. Brazos River, east to Atlantic, north to 42°. 17. *V. palmata*, Michx. Along streams, southern Illinois southward. 18. *V. monticola*, Buckley. Tops of cretaceous hills, south-western Texas.
- SERIES 7. CINERASCENTES (Planchon).—19. *V. Virginiana*, Munson. Mountain valleys, West Virginia. 20. *V. Berlandieri*, Planch. Cretaceous soils, south-west Texas. 21. *V. cinerea*, Engelm. Bottoms, south-west Texas, east to Atlantic, north to 40°. *V. cinerea*, var. *Floridana*, Munson. 22. *V. Caribæa*, D. C. West Indies and eastern Mexico, bottoms. 23. *V. Blancoii*, Munson. Sierra Madre Mountains, Guadalajara.

SECTION II. PUNCTICULOSIS, Munson.

- SERIES 8. MUSCADINIÆ (Munson).—24. *V. rotundifolia*, Michx. Southern States. 25. *V. Munsoniana*, J. H. Simpson. South Florida.

I offer the foregoing conspectus as my classification of American species of *Vitis*, and with it I send some estimate of the relative horticultural value of each.

Inasmuch as this classification does not entirely agree with others it may not be out of place to give some account of my preparation for the work. In the first place, I have taken the pains to visit each species, as far as possible, in its native habitat, to search out there the best plants in vigor and quality, to plant these together in a vineyard for comparison and study, to take notes of the distribution, altitude of locality, soil, habit and all botanical characteristics in every stage of the plant from the seed up to the fully developed vine, with critical notes and drawings at every stage and season. Besides this, I have hybridized nearly every species with one or many others and have noted the effects. Again, I have corresponded extensively with persons who have cultivated any of the native species either in pure or hybrid forms, and have obtained specimens of their best discoveries and hybrids, as well as botanical specimens from all quarters of North America, including Mexico and Jamaica. I have studied the leading herbaria in the United States which have important collections of the *Vitis* species, including the herbaria at Harvard, at the Academy of Science in Philadelphia, at Washington, and Engelm's collection at St. Louis. I have tried to study all the leading authors of the synonymy, although it is hopeless and inexplicable in many cases. I have attempted an exhaustive monograph upon the native Grapes of North America for the Department of Agriculture, which was written out first in 1887, and has been subsequently two or three times revised, and have been directing the work of an artist in painting accurately the growing shoots, full grown leaves, the flowers, male and fertile, etc., so as to give such complete illustration that even a novice may not err in the species when the work is finally published. My vineyard here contains growing specimens of every North American species of *Vitis* except *V. Californica* (which has been tried often, but as often perished by mildew) and *V. Caribæa*.

I have the species from Guadalajara, considered by Mr. Sereno Watson as *V. Caribæa*, and for a time considered by myself a variety of *V. Caribæa*, but now, after another season's growth, I am compelled to rank it a distinct species, as it develops specific characteristics not found in *V. Caribæa*. When I first obtained this in 1887 I thought it distinct, and had named it *V. Blancoii*, after Señor Luciano Blanco, of Guadalajara, who discovered it in the Sierra Madre Mountains. I shall hold to this name, as it appears now a good species, more clearly separated from *V. Caribæa* than is *V. cinerea* from *V. Berlandieri*, both recognized by our best Grape botanists.

There is not a species of the American Grapes which cannot by hybridizing and selecting be brought up to a fair degree of excellence as either table or wine fruit. One is astonished at the ameliorating effects of one cross in eliminating bad qualities and developing good ones. For example, a wild hybrid of *V. Labrusca* and *V. cordifolia* (the fruits of which are almost uneatable when pure), found growing in the woods in Roanoke County, Virginia, has produced seedlings which bear fine, large grapes, without pulp, foxiness or pungency.

V. rupestris has been used extensively, hybridized with *V. Lincecumii*, by H. Jaeger and myself, and with some other species less extensively, with the happiest results in producing very fine red wine grapes, and in some cases very good table grapes of pure, pleasant flavor.

V. riparia enters into many varieties in cultivation—in Taylor, Clinton, Montefiore, Elvira, Missouri Riesling and a host of others, combined with *V. Labrusca*—but too small of itself to be valuable. Some hybrids of *V. riparia*, from central Minnesota, with Concord, are about as large in berry and bunch as Champion, and earlier and better, and have endured unprotected a temperature of forty and fifty degrees below zero, and yet bore well. This species must enter into all varieties desired to endure the extreme winters of the north-west.

V. Solonis, with me, has been combined numerously with *V. Lincecumii*, *V. rupestris* and *V. riparia*, producing a peculiar class of grapes, without pulp and skins "thin as silk," juice always very highly colored violet and flavor very rich, sprightly, vinous, though often too acid.

V. Doaniana is generally a better grape in the wild state than Clinton and larger. It has great capacities in the hands of a skillful hybridizer, and will endure great heat and cold.

V. Arizona is the least promising of all the species for improvement in fruit, unless varieties specially adapted to the arid region of the southern Rocky Mountain region are desired. The quality is fine, but the fruit is very small, and the vine a feeble grower, even in this region.

I have one wild hybrid of *V. Girdiana*, with *V. vinifera*, which has clusters a foot long, and small to medium very sweet fruit. But it can hardly endure the mildew or cold of this region. This and *V. Californica* could be of no use east of the Rocky Mountains. They both are more tender every way than *V. vinifera*.

V. Champini produces a medium sized black grape often of fine vinous flavor, and has great vigor, hardness and constitution. For dry, hot regions, and limy soils, it offers a most excellent basis for a grand strain of varieties. It endures cold, too, to five to ten degrees below zero, but is affected somewhat by mildew in low, damp regions. *V. candicans* bears a horrible fruit for eating, owing to the biting pungency of the skin and the tough pulp, but the vine has great constitution for a hot country and limy soils. Though I have some fair hybrid Grapes with this, yet I think it time wasted to use it when we have so much better blood in other species. *V. coriacea* is a much more refined species, and some wild hybrids of this, with *V. Simpsoni*, from Florida, are quite good, but cuttings of *V. candicans*, *V. coriacea* and *V. Simpsoni* can be rooted only with the greatest difficulty.

Everybody knows the coarse *V. Labrusca*, which in its pure or hybrid varieties supplies almost the entire country east of the Rocky Mountains. It is a wonder that so good results have been obtained from this miserable "Skunk Grape." It is a pity that so much effort has been wasted on it while blood of quality so superior for every purpose can be commanded in other species.

V. Lincecumii, the large-fruited tribe of the *Æstivalian* series, has given some grand results in the careful hands of H. Jaeger and with me. It would take a fair sized catalogue to describe all the really good hybrids I have of this species, with *V. rupestris*, *V. Bourquiniana*, *V. Solonis*, *V. Labrusca*, *V. cinerea*, *V. cordifolia*, *V. vinifera*, etc. Suffice it to say that some of these, with grand vigorous vines that can endure twenty to twenty-five degrees below zero, have fruit that will stand critical tests with the best of *V. vinifera*. *V. bicolor* is capable, I am quite sure, of giving rise to a worthy tribe of pure varieties for Wisconsin, Michigan, etc., where it grows wild, as it is closely allied to *V. Lincecumii*.

V. æstivalis, another branch of the family, is already known to vineyardists in the Norton's Virginia, and with it there are quite a number of hybrids. I have several of these, some beautifully white and yellow, but not giving nearly such good results as my *V. Lincecumii* hybrids. *V. Simpsoni*, of south Florida, is the most peculiar member of this series, and is possessed of a much more tender pulp than *V. æstivalis*, and without the excessive astringency peculiar to the genuine *V. æstivalis*. But it is very sensitive to cold. It will probably become a valuable element in a race of hybrids peculiarly suited to Florida and the Gulf Coast. But its felty leaves are much attacked by leaf-rollers.

V. cordifolia, *V. palmata* and *V. monticola* have very smooth, glossy leaves never attacked by leaf-rollers, but the fruit is small and late and very seedy. However, *V. monticola* has a very sweet and peculiar flavor, and may yield something excellent in hybrids intelligently made. I have already mentioned some good hybrids with the unpromising *V. cordifolia*, or "Frost Grape."

V. Virginiana is a new species which I have obtained frequently from the high Appalachian valleys far down in Virginia. It appears to link the *Cordifoliae* series to the *Cinerascentes* in the east, as *V. Berlandieri* does in the far south-west. I had vines of this for seven years, not knowing where to put them in classification; till this year they have fruited, and prove to be different specifically from other species. The leaves are small, of a clear, lively green, somewhat pubescent, especially along the ribs; the young wood is angled as in *V. cinerea*, but becomes round and smooth at maturity, as in *V. cordifolia*. The clusters are very compound and compact, with very small berries of a dark purple color, covered with a thin bloom when ripe. The berries are very acid till quite ripe, then sprightly vinous. They ripen just before those of *V. cordifolia*, and two to three weeks earlier than those of *V. cinerea*. The seeds are very small, with scarcely any beak, cholera and raphe generally sunken, while in *V. cordifolia* and *V. cinerea* they are prominent. This species has never been published, so far as I am aware. *V. Berlandieri*, from the cretaceous soils of south-west Texas, is the species so much in demand just now in the chalky soils of France, especially in the Charente Inferieure, where no other species will grow without "chlorosing" (yellowing) from excess of lime; hence they use it there as a stock. But it has a very large cluster of rich, though remarkably small, fruit. It can easily be developed by hybridizing, as experiments have already proved. The leaves

are of a dark green, very glossy surface, so that the leaf-roller does not prey upon them. Its greatest difference from *V. cinerea* is in the dark green, glossy leaves, those of *V. cinerea* being wrinkled, dull green, pubescent and tomentose. The clusters and fruit are much alike. *V. Caribæa* has a rounder, broader leaf, with more rusty pubescence and tomentum than has *V. cinerea*, and the clusters are still larger, with smaller berries. It is too sensitive to cold to be of any service in this country. *V. Blancoii* has smaller, more cordate leaves than either of the three last-named species, and has the lower face densely tomentous, with snowy white wool and clusters nearly simple and much smaller than *V. cinerea* or *V. Caribæa*; but the berries are larger and of a different flavor, and the young wood is less angled. It can only be carried over winter here by careful protection, being much more tender than *V. vinifera*; but mildews do not damage it much.

V. rotundifolia is the common Muscadine of the south, and is much prized by old southerners, in such varieties as Scuppernong, Thomas, etc., which have three to nine berries in a cymose cluster. The berries are very large, with a very thick, tough skin and a large, tough pulp, and have a peculiar musky flavor. They are of a dull, rusty yellow in Scuppernong, or dull black in others. The seeds are very large, resembling Coffee-grains. Some hybrids have been produced, but are not promising. The species is remarkably free from all manner of diseases and insect attacks.

V. Munsoniana is of a very slender, weeping habit, leaves smaller, with fewer, larger teeth than in *V. rotundifolia*. It begins to bloom later and continues to bloom on till frost. The clusters are of the cymose character, but bear from ten to twenty or more berries, which are small, with shining black skin, rather thin, pulp melting, filled with acid juice without the rustiness of Muscadines. The seeds are very small. This species is fully as distinct from *V. rotundifolia* as is *V. rupestris* from *V. riparia*, or *V. cinerea* from *V. Caribæa*, if not more so, and, to be consistent, it should be recognized. It appears somewhat more nearly related to the true "bunch-grape" than *V. rotundifolia*, and may be valuable to hybridize for the south.

For beautiful effect as ornamental vines in bowers running over arbors and the like, *V. palmata*, *V. monticola* and *V. Munsoniana* are exquisitely delicate, graceful and beautiful. *V. palmata* is hardy in central Illinois, *V. monticola* will endure nearly as much, *V. Munsoniana* will live almost anywhere in the southern states.

Dennison, Texas.

T. V. Munson.

Drought-enduring Trees.

WE have had in central Iowa during the past summer the culmination of a three-year shortage in rainfall. At the commencement of spring growth we were over forty inches short of the normal supply during the three years past, and up to the first of September our lawns have had the aspect of California during the dry season. Under these circumstances I wish to note some not well known trees and shrubs which have endured our recent test winters perfectly, and have made fine, luxuriant growth during the drought where most native trees and shrubs have hardly held their own.

CUT-LEAVED BIRCH.—Our trees are from Moscow, where this tree has been long grown, and where it possibly originated from the pendent, small leaved species from the Amur Valley (*Betula Amurensis*). Our specimens have been models of health, and have made rapid growth without apparent regard to scanty rainfall. As this has also been true over the state with specimens propagated from the west European stock, I suspect it was originally obtained from east Europe.

BETULA ALBA VERRUCOSA.—Plants from east Europe of this fine variety were planted eight years ago in blue grass sod on the campus. They are now handsome, erect trees, from thirty to thirty-five feet in height. While the native Elms by their side show little recent growth and dead branches, these Birches have been growing like Russian Poplars and Willows.

ELÆAGNUS ANGUSTIFOLIA.—This beautiful silver-leaved tree of the east has also made luxuriant growth. When loaded with flowers its fragrance has been noted at a distance of over forty rods.

ALNUS RUGOSA.—A dry climate species that appears to delight in a dry air and dry soil. In expression it is a better tree than the Scotch Alder, which does not endure such summers on dry soil.

ULMUS EFFUSA.—This species is much planted to arrest snow sweeps along the Russian railways. It has large, handsome leaves, a dense habit, and is by all odds the handsomest Elm we have. It has made luxuriant growth when our natives have suffered severely from drought.

PYRUS ARIA LACINIATA.—The White Beam of west Europe has not endured our recent summers or winters. But this eastern variety has been perfect, a rapid grower, and its beauty of foliage has attracted much attention.

VOLGA OAK.—I picked up some acorns under a beautiful Oak on the bluffs of the upper Volga in 1882. Trees from these, twice transplanted, are now twelve to fourteen feet in height, with dark green cut leaves of great beauty. In rapidity of growth during our dry period they have been a thing of wonder. It is said to be a variety of *Quercus robur*; but it is peculiar in expression, and the acorns are borne on thin, tough peduncles from three to four inches in length.

PHELLODENDRON AMURENSIS.—The Phellodendron from China and Japan is as tender here as the common Peach. But this species as obtained from Russia appears to be hardy, handsome and defiant of drought.

PYRUS TORINGO.—A species of the Apple from east Europe with remarkable, thick, rugose leaves that hold their color until very late in the fall. Severe early freezing does not appear to affect the health or color of the handsome foliage. It is a beautiful, round-topped tree, with pretty flowers and long stemmed fruit. It is said to be the original form of some of the Transylvanian Apples.

SALIX LAURIFOLIA.—As introduced from east Europe, this does not appear to be identical with that of the eastern nurseries. It is a handsome, round-topped tree that few recognize as a Willow until the buds and twigs are examined. It appears to delight in heat and aridity of soil and air.

ACER GINNALA.—This makes a pretty, small tree in our climate, which in the fall puts on all the gorgeous colors of the Japan Maples, which will not live with us.

RHUS COTINUS.—As introduced from the eastern nurseries the Venetian Sumac will not endure our winters. But the variety from extreme east Europe is perfect.

Iowa Agricultural College.

New or Little Known Plants.

Rosa Watsoniana.

THIS curious Rose, of which a figure appears on page 477 of this issue, has been grown in the Arnold Arboretum during the last dozen years. It came to the Arboretum from the garden of Mr. Edward S. Rand, in Dedham, Massachusetts, who had obtained it, if I remember rightly, from a garden in Albany, New York. It was supposed to have been brought from Japan and to be a cultivated form of a variety of *Rosa multiflora*. Its Japanese or Chinese origin is probable, but Monsieur Crépin, whose knowledge of roses is unrivaled and to whom specimens from the Arboretum have been submitted, points out certain characters which separate it from that species and from another east Asia species of the same section (*Synstylæ*), *R. anemonæ-flora*, to which, however, it is closely related. The fact that the plants although perfectly hardy and flowering profusely every year produce no seed, would seem to suggest some long cultivated abnormal form from a Japanese garden, a view which is further strengthened by the fact that wild specimens of this plant have not been collected.

*Rosa Watsoniana** is a graceful plant with slender semi-prostrate stems armed with slender recurved spines. The leaves are three or sometimes five-foliolate with pubescent glandular petioles armed with minute recurved spines, and with very narrow, adnate, entire, hairy stipules. The leaflets are narrowly lanceolate or linear, contracted at the two ends and at the apex into a long slender point; they are pubescent on the lower surface along the midrib, entire, with sinuate wavy margins, and are two or two and a half inches long, the broadest less than a quarter of an inch wide. The inflorescence is many-flowered, pyramidal, four or five inches long, three or four inches broad, the primary bracts awl-shaped, hairy, deciduous with the opening of the flowers. The slender pedicels are jointed and provided with minute membranaceous, caducous bracts. The flower-buds are ovoid and slightly hairy. The sepals are narrowly lanceolate, entire, subulate-pointed, and covered thickly on the inner surface with dense pubes-

cence. The petals, which are obovate, pointed at the apex, entire, pale rose-colored, form a corolla less than half an inch across when the flower is fully opened. The column of united styles is slender, elongated, and glabrous. The flowers open about the middle of June.

Rosa Watsoniana possesses considerable interest as a curiosity among Roses, but little beauty or value as a garden plant from the ordinary horticultural point of view; and it will probably never be very much grown, either for its remarkable foliage or its minute flowers. It has proved, however, an admirable stock for several of the Hybrid Perpetual Roses, and has already been propagated to a considerable extent for this purpose in the neighborhood of Boston.

Our illustration is from a specimen grown in the Arboretum.

New Orchids.

EPIDENDRUM VITELLINUM FLORE PLENO.—A very interesting case of doubling has occurred in the well known *Epidendrum vitellinum*. A plant in the collection of Mr. Raphael, of Castle Hill, Englefield Green, recently produced five racemes, every flower of which was double and quite regular. The lip was replaced by an ordinary petal, and the column was broken up into six small petal-like segments, which occupied the centre of the flower, thus producing a perfectly regular double flower of twelve segments. Whether the peculiarity will prove permanent remains uncertain.—*Gardeners' Chronicle*, July 26th, p. 103; August 2d, p. 123.

MASDEVALLIA COSTARICENSIS, Rolfe.—A pretty little Masdevallia, introduced from Costa Rica by Messrs. F. Sander & Co., of St. Albans. It is allied to *M. Reichenbachiana* and *M. marginella*, especially to the latter, as the flowers are much of the same color, being white with yellow tails, and the nerves of the lateral sepals of the same color. The peduncle bears two or three flowers in succession.—*Gardeners' Chronicle*, August 16th, p. 183.

CYPRIPEDIUM × YOUNGIANUM, Rolfe.—This handsome hybrid, mentioned on page 428, is fully described in *Gardeners' Chronicle* for August 16th, p. 183.

MASDEVALLIA LOWII, Rolfe.—This distinct and pretty species of the Saccolabiata section, mentioned at page 133, was awarded a first-class Certificate by the Royal Horticultural Society on August 12th.—*Gardeners' Chronicle*, August 16th, p. 197.

MASDEVALLIA × AMESIANA.—A hybrid raised between *Masdevallia Veitchii* and *M. towarensis*, and exhibited by Messrs. F. Sander & Co., of St. Albans, at a meeting of the Royal Horticultural Society on August 12th. The flowers are described as apricot-colored.—*Gardeners' Chronicle*, August 16th, p. 197.

PHALÆNOPSIS MICHOLITEZII.—A new Phalænopsis, somewhat allied to *P. tetraspis*, which was exhibited by Messrs. F. Sander & Co. at a meeting of the Royal Horticultural Society on August 12th, when a Botanical Certificate was awarded it. The flowers are greenish white, the lip white with coarse hairs and a yellow crest, and the leaves ovate, shining green and about seven inches in length.—*Gardeners' Chronicle*, August 16th, p. 197.

CYPRIPEDIUM × H. BALLANTINE.—A hybrid between *Cypripedium purpuratum* and *C. Fairieanum*, exhibited by Messrs. James Veitch & Sons, of Chelsea, at a meeting of the Royal Horticultural Society on August 12th, and to which a first-class Certificate was awarded. It is of dwarf habit, with much of the reticulations of *C. purpuratum* on the dorsal sepal, the petals greenish brown, with lines of crimson and the lip of similar coloring.—*Gardeners' Chronicle*, August 16th, p. 197.

CORYANTHES BUNGEROTHII, Rolfe.—A very fine species of Coryanthes, rivaling *C. Fieldingii*, whose flower Dr. Lindley affirmed to be the largest yet known among Orchids. It was sent from Venezuela in 1888 by M. Bungeoth to Messrs. Linden, L'Horticulture Internationale, Brussels, in which establishment it flowered in May of the present year. It is one of the most remarkable Orchids in existence, both in the structure of the flower and in the economy of fertilization. It is described and finely figured in *Lindenia*, vol. vi., t. 244; also described in *Gardeners' Chronicle*, August 23d, p. 210.

DENDROBIUM GALLICEANUM, Linden.—A very beautiful Orchid with the habit of *D. thysiflorum*, to which it is obviously allied. The sepals and petals are white, and the lip canary yellow, with fimbriate margin. It was imported with *D. thysiflorum* by Messrs. Linden, L'Horticulture Internationale, Brussels.—*Lindenia*, vol. vi., t. 241. R. A. Rolfe.

*Crépin, *Bull. Bot. Soc. Belg.*, xxvii, part 2, 98; *Jour. Royal Hort. Soc., London*, xi, part 3, 2. *Revue d'Horticulture Belge et Étrangère*, xiv, 183, f. 16.

Foreign Correspondence.

London Letter.

LAST Tuesday an opportunity was afforded to horticulturists interested in the subject to compare the two garden races of Gladioli, known by the names of the Gandavensis and the Nanceianus races. This last is of only recent origin,
